2. Diagnosis of Tuberculosis in Children.—Henry D. Chadwick and Roy Morgan summarize the essentials for a minimum standard necessary in the diagnosis of tuberculosis in children by emphasizing the importance of symptoms indicating tuberculin absorption, namely: Weakness, undue fatigue, fever, poor appetite, failure to gain, or loss of weight, and nervous irritability. The

local symptoms are cough, hoarseness and occasionally streaked sputum. The usual physical signs are dullness in the interscapular region radiating into the apices at the back, frequently not elicited in front. There may or may not be changes in the respiratory sounds. Râles may or may not be present. Symptoms both constitutional and local, together with a history of exposure, are to be given greater weight in making a diagnosis of active tuberculosis than the presence or absence of physical signs. Percussion is more important than auscultation. It must, however, be borne in mind that a thickened area in the lung or region of the bronchial glands does not in itself mean active tuberculosis. It may be a healed lesion that needs no treatment. Such thickening may also be caused by other diseases than tuberculosis. The child showing constitutional symptoms, even without local signs of disease in the chest, should be considered suspicious, kept under careful observation and hygienic treatment instituted in the home. The case with signs in the chest, without constitutional symptoms, indicates an old inactive infection that needs no treatment. Individualization and common sense must be used to weigh all the factors in the case, and, with experience as a guide, few errors in diagnosis will be made.

2. A Bariumized Test Meal With Combined Fluoroscopic and Chemical Study as a Means of Rapid Preliminary Stomach Diagnosis.—G. W. McCaskey states that the chemical processes of gastric digestion have been studied very minutely and extensively for a number of years, these studies being largely limited to the phenomena with the Ewald breakfast. This test meal does not call out, and therefore does not measure the reserve powers of gastric digestion, and is consequently of somewhat limited value in the general field of gastric diagnosis. Such an enormous literature has been built upon its widespread clinical use that it must be regarded as of decided value for comparative purposes, while fully realizing its limitations. It is undoubtedly true that an average normal stomach will usually behave in a certain manner under the stimulus of the Ewald test breakfast and important information concerning secretory and even motor conditions may be obtained. McCaskey considered that if a rapid fluoroscopic method could be combined with this test meal much preliminary information could be quickly obtained. Such an examination made under favorable conditions with an empty stomach would in many cases furnish all the *x*-ray data necessary for diagnosis. This could be done in about an hour's time when a rapid survey of the case is desirable. In conjunction with and during the progress of other preliminary investigations, such as the taking of the anamnesis, the physical, blood, and urine examinations, and would rapidly place the clinician in possession of what might be called a skeletal outline of the most important motor secretory and topographical facts. Further fluoroscopic or even radiographic methods will be used when required for the purposes of a satisfactory working diagnosis. The patient is placed behind the fluoroscopic screen and given to drink two ounces of water in which is stirred up ten to twelve grams of barium. The precise topography and position of the stomach can be accurately noted and recorded on tracing paper if desired, as well as any abnormal condition present. Before removing the patient from behind the screen he is made to drink a test meal composed of one and one-half ounces of cream of wheat, boiled in a sufficient amount of water to measure ten ounces when cooked. The movement of the barium in the pyloric antrum shows the amount of depression from the weight of the test meal, which gives some information regarding the mobility and tonicity of the stomach and its supports. Pyloric function, especially patency and peristalsis, can be further studied at this point if the symptoms suggest that this is necessary; if not, the test meal may then be treated in the ordinary manner either by its fractional removal through an Einhorn duodenal tube which has been swallowed with the test meal or by the ordinary stomach tube at the close of the conventional one hour. McCaskey points out that by the fluoroscopic observation of about one-third of an ounce of barium stirred up in two ounces of water in its passage to the pylorus, we can get an absolutely accurate outline of the position of the fasting stomach in a perfectly quiescent state without distortion by the weight of a heavy meal. Muscular tonicity is well indicated by the time that the barium lingers in the magenblase and the rapidity of the canalization of the stomach. The coincidence of a point of tenderness on pressure or a palpable tumor with the pylorus or other part of the stomach can be instantly determined. If chemical study of gastric secretion is desired, large quantities of barium cannot be used, as they inhibit the secretion of hydrochloric acid. The quantity above indicated only slightly interferes with secretion and the turbidity caused by mixing of the barium with the test meal does not substantially interfere with the titration for acidity. The delicacy of the Ufflemann test for lactic acid is diminished by about one-half. The test for occult blood is not perceptibly interfered with. In a very large proportion of cases, this technic with such modifications as the individual case or the judgment of the clinician may indicate is quite sufficient for the purposes of diagnosis and will either exclude serious organic lesions, or taken in conjunction with other available data, especially the anamnesis, indicate further study along the proper lines of clinical investigation. It is only by the routine use of fluoroscopy that the diagnostic aid of röntgenology can obtain that widespread use so desirable in the field of internal diagnosis.

2. Purulent Bronchitis.—J. A. B. Hammond, William Rolland, and T. H. G. Shore point out that the numerous cases of purulent bronchitis which have arisen at one of the bases in Northern France during the winter of 1916-17 have presented features of marked clinical and pathological interest. Patients suffering from this unusually fatal disease present a symptom complex so distinctive as to constitute a definite entity. During February and early March, while the outbreak was at its height, 45 per cent. of the necropsies in this area showed the presence of purulent bronchitis. The writers deal with this condition from three standpoints: (1) That of the clinician; (2) that of the bacteriologist, and (3) that of the morbid anatomist. Their conclusions are drawn as follows: (1) They are here dealing with an epidemic of a variety of purulent bronchitis. (2) For the following reasons they consider the cause of the disease to be the influenza bacillus; (*a*) The almost constant occurrence of this organism in the sputum; (*b*) its presence in the pus of the affected bronchioles; (*c*) in some typical cases it occurs apart from the presence of any other organism; (*d*) the outbreak of the disease in epidemic form at the time of year when influenza epidemics are most common and while one was actually in progress; (*e*) the

marked signs of toxic poisoning which are found during life and post mortem. (3) There are well marked clinical features which distinguish these cases from ordinary cases of bronchitis. The most prominent are the characteristic sputum, which is mucopurulent, and of a greenish yellow color, and thick; the extreme tachycardia, the cyanosis, the course of the temperature, which is sustained and high until the ante-mortem fall, and the extremely high mortality. (4) Treatment has so far been unsatisfactory. The most encouraging results have been obtained by use of a steam tent. Vaccines have not yet had a trial, but it is unlikely, in view of the blocked condition of the bronchioles, that they would be of great benefit. (5) The morbid anatomy consists of three groups of changes. (*a*) The lung condition: Marked purulent bronchitis, the smaller bronchi being filled with thick pus, from which air is notably absent. In some cases secondary bronchopneumonia and œdema, pleurisy, and emphysema are common. (*b*) Evidence of toxemia: Especially seen in kidneys, spleen, liver, lymphatic glands, and heart muscle. (*c*) Signs of right side heart failure and passive congestion. Some cases die of the toxemia and others of the cardiac failure. (6) The histological changes are those of an acute purulent bronchitis affecting the smaller bronchi with or without some surrounding catarrhal pneumonia. Degenerative changes are seen in other organs, notably in the kidneys, where the appearances of a toxic nephritis may be found.

10. Studies on the Cause and the Treatment of Bronchial Asthma.—I. Chandler Walker tells of the investigations carried out for the past two years at the Peter Bent Brigham Hospital, Boston, in the study of the causation and treatment of bronchial asthma. In the report given he has limited his study to the first 150 patients, because all of these were observed during one complete year, from May to May. Of this series of 150 cases, eighty-three, or 55 per cent., were sensitive to some protein. The horse—horse dandruff and hair—was chiefly responsible for bronchial asthma in 20 per cent. of these cases, the wheat proteins, *Staphylococcus pyogenes aureus*, and the early pollens were each responsible for asthma in 15 per cent. of the cases, the late pollens in 10 per cent., the cat in 5 per cent., *Staphylococcus pyogenes albus* in 3 per cent., and in the remaining 10 per cent. of these cases several proteins were the cause of asthma. Many patients were sensitive to more than one protein, thus making the above percentages not absolutely accurate. A few words will dismiss the nonsensitive patients. Of the 150 patients in this series, 45 per cent. failed to react to any protein that was tried. Besides the skin test, other facts would seem to warrant the division of bronchial asthmatics into two groups. No patient that had onset of asthma after the fortieth year of age has given a positive skin test, and one-half of the sensitive patients began to have asthma previous to the age of twenty. Quite opposite to these statements is the fact that 40 per cent. of the nonsensitive patients had onset of asthma after the fortieth year of age and only 15 per cent. had onset of asthma previous to the age of 20. Only 1 per cent. of the sensitive patients had cardiorenal disease; whereas 20 per cent. of the nonsensitive patients had this complication. Chronic bronchitis was a complication in only a small number of the sensitive patients, but it was a complication or cause of asthma in nearly all of the nonsensitive patients. These statistics thus seem not only to separate bronchial asthma into two types, namely a sensitive and a nonsensitive, but they are of value in determining the cause and the treatment of bronchial asthma. For instance, the patient that has onset of bronchial asthma early in life is usually sensitive to some protein, chronic bronchitis is not a usual complication, and cardiorenal disease is a rare complication. Contrary to the above, the patient that has onset of asthma after the age of 40 is not sensitive to proteins, chronic bronchitis is almost always a complication or cause, and cardiorenal disease is frequently a complication or cause of asthma. With the serum of the sensitive patients complement fixation and precipitin reactions were done, using the protein to which they were sensitive as an antigen. These tests proved to be of no help in diagnosis, prognosis or treatment. The treatment of the nonsensitive group of bronchial asthmatics has been disappointing. About one case in every six has been relieved of asthma by vaccines made from a diphtheroid organism. This particular type of organism was selected because it was usually the predominating one in the patient's sputum when the sputum was cultivated on plain agar. The sensitive patients offer a very good prognosis. If the patient is sensitive to the food proteins, omission of these foods from the diet is followed by relief from bronchial asthma, unless the patient has considerable bronchitis, which may require attention, and vaccines made from the predominating organism in the patient's sputum greatly benefits or relieves this condition. They have treated their wheat cases with subcutaneous injections of the wheat proteins, but have been unable to increase the patient's tolerance for these, and the eczema that is a frequent complication in these cases has been made worse. Therefore omission of the food proteins from the diet seems to be the simplest treatment for this type of bronchial asthma. Treatment with the amino-acids of the food proteins may be of benefit. Those patients who are sensitive to bacterial proteins are successfully treated with stock vaccines of that particular organism to which they are sensitive. These vaccines have been given at weekly intervals, in gradually increasing amounts, beginning with 200 million the first dose. Relief from attacks of asthma has continued for from four to six months after the vaccines were discontinued, and relapses have yielded to a second series of vaccines more quickly than to the first series.

3. The Chadwick Lecture on Mental Hygiene and Shell Shock During and After the War.—F. W. Mott, in discussing the treatment of shell shock, states that

in the early stages it varies to some extent in different individuals, according to symptoms and signs, but that there are some symptoms which are seldom absent in all true cases—namely, insomnia and terrifying dreams. He has found the continuous warm bath of great value in the treatment of these cases when they return from France. The bath is kept continuously at the temperature of the blood by a special mechanism of heat regulation; the patients are kept in the bath for a quarter to three-quarters of an hour, or even longer. The effect is most soothing on the nervous symptoms. A drink of warm milk added at bedtime, together with a bath, often suffices to produce sleep without hypnotics. If hypnotics are used less amount is required. Next the general bodily condition must be improved by nourishing, easily assimilated food and regular evacuation of the bowels. The severe headache requires an icebag and drugs which relieve neuralgic pains. After improvement begins, an interest in surroundings and everyday life should be established. Noise must be avoided, and quiet is demanded, but not loneliness. As soon as they are better, patients are encouraged to become interested in games; also there are popular concerts and popular lectures to divert the mind and produce an atmosphere of cure, which is very essential. Discipline is very necessary; laxity of discipline, over-sympathy and attention by kind, well-meaning ladies giving social tea parties, joy rides and drives, with the frequent exclamation of "poor dears," has done much to perpetuate functional neurosis in the British soldiers. The too liberal gifts of cigarettes have produced a cigarette habit in officers and men which is highly detrimental in these cases of war neurosis, especially in cases of irritable dilated heart. Those patients affected with a functional paralysis need much help and encouragement. Mott, in treating the immobile arm or leg, performs a number of associated movements with the afflicted member, telling the patient at the same time to help him by thinking of the same movement. After a little while the patient may be doing the main part of the movement himself. The greatest tonic for this type of cases is to tell the patient that he is not likely to be returned to active service, but that the aim of the treatment is to put him in shape for his previous occupation, or some work useful to the State, whereby he will not be a burden to himself or the community. Mott considers that if this method were adopted early, in a large number of cases known by an expert to be temperamentally unfit for military service, a great economic saving would be affected. Malingerers would have to be guarded against. He entirely approves of the natural methods of restoring function, but not by the machines now in use in some places, as they are wrong in principle and in practice. Associated movements as in the use of parallel bars, the climbing rope, football, Indian clubs are all beneficial, as the mind is also concentrated on the limb as well as the means of procuring the movement, and the sound limbs are exercised at the same time. Diversion of mind by useful occupation, both in workshop and garden, have been successful in the cure of these disabled soldiers. Mott is convinced that occupation in the open air, while decidedly beneficial treatment for nervous cases in the convalescent stage, is not always popular with a certain type of case. Each case has to be studied as to work, hours, fatigue, and general sense of wellbeing. The money earned by these men should be supplemented to the pension money or gratuity.

Le Progrès Médical.

July 8, 1917.

Adrenaline in Hemorrhages and Congestions.—Satre first discusses the vasoconstrictor property of suprarenal extract. Nothing can be more clean-cut than this action, which can readily be studied under local application to a mucous surface. In experiment on animals, if some of the extract is thrown into the renal artery, the kidney contracts energetically. Thrown into the jugular vein, it causes contraction of all the arterioles in the body, and the blood pressure is increased. Hence, in free hemorrhages from mucosæ or in simple congestion of the latter, local application of the extract is quite sufficient for hemostasis. In a parenchymatous hemorrhage, in the course of an operation, the indication is filled in the same manner. The extract is indicated locally in hemorrhoids because of its power of contracting both the dilated and normal vessel. In hemorrhage from the intestine, however, should the drug be injected into the general circulation in the belief that it will exact a localized hemostasis? In theory no; for the contraction of all the arterioles raises the blood pressure, which in turn should tend to increase the hemorrhage. We must, however, bear in mind that if the later is capillary in origin the capillary blood pressure will be low when the general blood pressure is high. All therefore depends on the character of the hemorrhage, for if the source of the blood is an artery the extract will aggravate the hemorrhage. In the clinic this problem has not yet been fully worked out. In hematemesis the drug is, of course, able to exert its local action. In hemoptysis the systemic injection gives good results, although for reasons just mentioned the mechanism is not obvious. But various authorities prefer to inject the extract into the trachea or directly into the disease focus.

Euthanasia.—M. G. relates that one army surgeon, at least (Bertholey), has written a thesis on euthanasia (Lyon, 1917), in which he agitates the question of the right of the military practitioner to anticipate death in those suffering intensely and with no hope of survival. This problem has been discussed in the United States and Canada in civil practice; while in Europe, Italy is mentioned in the same connection. As a military problem the same objections hold good. The patient who has suffered atrociously may lose his pains before death. Euthanasia is an ill-chosen term for physical suffering alone is comprised, despite the fact that mental anguish remains as a result of regret to die, of the uncertainty of the future, etc. In most cases we know that the mental processes become obscured before death, and that as a rule the latter occurs with patient unconscious. In but two out of thirty-five dying soldiers was consciousness clear. These two suffered acutely up to the last, and the patients could have been put out of their misery, but such intervention would have inverted all our conceptions of civilization.

Archives Médicales Belges.

February, 1917.

Injections of Peptones in the Treatment of Typhoid Fever and Other Infections.—Wolf first mentions the sharp reaction which follows the injection into the blood of albumoses and peptones. Years ago the author showed that injections of the latter under the skin or into the muscles could favorably influence hemorrhagic diathesis and paroxysmal hemoglobinuria. During the past two years he has been using it in typhoid fever in the interest of the prevention and treatment of intestinal hemorrhage, its most fatal complication. In cases likely to develop these hemorrhages, minute extravasations of blood may readily be produced artificially by slight punctures, friction, etc. In such cases a 5 per cent. concentration of peptone solution is injected into the buttocks, 10 cm. at a dose, repeated daily, if necessary, and every other day in the absence of special indication. In his series of over 170 cases of typhoid but three developed hemorrhage under this treatment. Only one of these was severe, and in none did hemorrhage reappear. In connection with this use of peptone the author noted improvement in other respects. Two histories are given which show that the fever fell at once upon injection. However, we could hardly expect such a result save late in the course of the fever. Defervescence was not complete, but the author was emboldened to increase the dose, and also test the results of intravenous injection. The dose injected into the muscles was increased to 12, 15, and even 20 cm. of the 5 per cent. solution, without any detrimental effects. In order that the fever be lowered permanently the injections must be repeated every second day. The same general result was obtained by intravenous injections, 10 to 15 cm. of a 10 per cent. solution. A marked general reaction is observed which comprises tachycardia, headache, cough, etc., all of

which subside quickly. An overdose is shown by the development of violent tachycardia, respiratory distress, cyanosis, violent headache, severe cough, nausea, and vomiting (anaphylactic shock). This syndrome can be prevented by proper technique—very slow infusion under pulse control. Both the immediate and more remote effects of the intravenous injections upon the entire course of the disease are very favorable. The mechanism of action is unknown. Blood cultures continue to give positive results throughout. The author has injected peptones in syphilis and tuberculosis, but as yet it is too early to speak of results. Peptones would prove a very convenient remedy. They sterilize at 120° C., are readily procurable, and despite the initial reaction are readily assimilable. They can be injected for months without the development of intolerance.

Annales de Gynécologie et d'Obstétrique

May-June, 1917.

On the Determination of the Date of Fecundation in Women.—Ancel and Bouin refer to the current opinion that the ovum can be impregnated only for a very brief period after rupture of the follicle. This period is probably not above two days at most. But there is a difference of opinion as to when this rupture occurs. One faction places this at the end of the menses, while the other believes it to take place from twelve to fourteen days before the menses, or, what amounts to the same thing, 14 to 16 days from the beginning of the previous period. Each view is based in part on theoretic considerations. The first named is the reflex theory of menstruation, while the second is the internal secretion theory. The former is the old classic view which originated before the days of endocrinology. The more recent view is based on the belief that the internal secretion of the corpus luteum determines menstruation. This structure is formed at the expense of the follicle and pours certain hormones into the circulating blood. When the corpus has attained its full development the congested mucosa of the uterus begins to bleed, and when it has begun to undergo involution the flow ceases. The evidence in favor of the older theory was scanty and based chiefly on autopsy finds. Further, not much was known of the intimate nature of the corpus luteum. Data which uphold the modern theory have been supplied by Fraenkel in Germany and Villemin in France. It has been proved that in full menstruation one never finds a mature follicle, but a corpus luteum in a period of *status;* from five to six days after the menses one finds a corpus luteum in the midst of involution and also a follicle in its incipient stage of development; from fourteen to fifteen days after the menses the new follicle is at the point of rupture, and finally from seventeen to twenty-two days after menses another corpus luteum is in process of development.

The Amount of Blood Lost During the Menses.—Lahille found after a series of experiments that the statements made on this point by classical authors are somewhat too high. Estimating the amount of blood by the quantity of its constituent iron, he finds that 25 per cent. of women lose not over 20 gms., 50 per cent. from 50 to 55 gms., and the remaining 25 per cent., 65 gms. and upwards. When the amount is over 80 gms. the character of the menses is sensibly affected—clinically it is menorrhagia. At the acme of a period the daily loss may be 15 to 20 gms. This is seen to occur in the medium class. In a period four or five days long the loss of blood occurs chiefly on the second and third days, when the total loss will be 30 to 40 gms. On the first, fourth and fifth days the loss will average not over 5 gms. daily. The author thinks that his finds should be checked up by some other method of analysis.

Revue de Laryngologie, d'Otologie et de Rhinologie

June 30, 1917.

Leeches in the Larynx.—Navarro, of Cordova, gives a systematic account of this condition, which is often discussed as a matter of individual experience. The author, who is director of the municipal laboratory, has made special investigations into the subject. Leeches are "swallowed" during the period June-October, inclusive—very rarely during other months—and chiefly by field laborers, who drink water as they find it. In many cases the victims realize what has happened. The leech may attach itself to any one of a number of places, but the author is concerned only with the intralaryngeal region, although the symptoms produced by no means indicate the point of attachment, which can be determined only with aid of the mirror In an extralaryngeal location close to the glottis the symptoms of hemorrhage, dyspnea, violent cough, etc., can be produced the same as in an intralaryngeal site. When the leech is implanted within the larynx no typical symptoms develop. There may in fact be no symptoms of any kind. In rare cases there is impending suffocation, although this could be due to laryngospasm. The amount of tolerance on the part of the larynx to the intruder may be phenomenal. In general the tendency is toward progressive dyspnea. Perhaps characteristic of an intralaryngeal location is a certain alteration of the voice, but this is rarely encountered. It is not due to any change in the vocal cords, but to the movements of the leech in contact with the latter. The amount of blood lost, irrespective of location, is sufficient to cause noticeable anemia in several days. The author has seen the animal in almost every conceivable location within the larynx and on the inferior surface of the epiglottis. If the leech simply blocks the larynx its removal should be easy. In certain deeper locations there may be free inspiration with expiratory dyspnea. It is a necessary consequence that the smaller the leech the more readily it can enter the larynx and, other things equal, the less disturbance it can cause. A small leech so attached as to escape the ordinary field of the mirror may become visible only after a prolonged search. In treating these cases the application of cocaine is unwise, as shown by Botey of Madrid. Some laryngologists have had the idea of anesthetizing the leech incidentally so that it might be coughed up, but this idea seems based on an erroneous conception. An anesthetized larynx would lose its reflex susceptibility and expulsive cough would be inhibited. The author uses no cocaine. By means of Krause's forceps, with transverse opening, the animal must be quickly grasped; celerity counts much for success. If a fold of mucosa is included in the bite of the forceps a new hold must be taken. If the leech is implanted below the cords the patient must take a deep breath as the forceps are inserted. A larynx which can tolerate the presence of a leech is usually tolerant to the forceps.

A New Type of Acute Articular Rheumatism.—Chantemesse and two others have announced the nosological separation of a polysynovitis with visceral complications and terminal enuphacopathy. The disease represents an infection due to an unlisted microorganism intermediate between bacteria and fungi: It has been named the *Mycobacillus synovialis.*—*La Presse Médicale.*

Synergism of Arsenic and Quinine.—Gautier states that the addition of a minute dose of arsenic to a dose of quinine makes it of value equal to that of the very large dose of the latter salt.—*Le Progrès Médical.*

Hours for Meals.—Amar disputes the claim of Bergonié that heavy meals at noon and 7 or 8 P. M. are inferior for utilization of food. The cumulative experience of the public sanctions these hours. Carbohydrates are utilizable 30 minutes after ingestion whenever taken, while utilization of protein is difficult for the first two hours after a repast.—*La Presse Médicale.*

Effect of the War on Italian Births, Deaths and Marriages.—The average annual number of marriages in Italy before the war was 266,000. In 1914 the number was 250,000. In 1915 this number fell to 186,000. Figures for 1916 are not yet available. In 1915 the birth rate was diminished by 22,000. The figures for 1916 have not been completed, but it is known that the decline will be very great. In the city of Naples before the war the mean figures for marriages were 4545; for births, 17,881; for deaths, 13,564. In 1914 the births amounted to 19,044; deaths, 13,247; marriages, 4233. In 1915 the marriages decreased notably (3203) without much change in the births and deaths. In 1916 the marriages showed only a slight decline (3043), but the births fell to 16,337, and the deaths rose to 14,086.

Book Reviews.

SANITATION IN WAR. By Major P. S. LELEAN, C.B., F.R.C.S., D.P.H., R.A.M.C., Assistant Professor of Hygiene, Royal Army Medical College. With an Introduction by Surgeon-General Sir Alfred Keogh. K.C.B., M.D., F.R.C.P. With 54 illustrations. Second Edition. Price, $2.00 net. Philadelphia: P. Blakiston's Son and Co., 1917.

THIS small textbook on sanitation in war embodies a series of lectures delivered by Major Lelean with the object of assisting newly joined officers to gain an insight into sanitary methods employed on active service. The lectures deal with physical fitness for war, antityphoid inoculation, the march, sickness in the army, the rôle of insects in war, medical organization, administration and duties in the field, some new departures in field sanitation, and water and water supplies. These subjects are dealt with one and all in an instructive manner.

NOTES ON MILITARY ORTHOPEDICS. By COLONEL ROBERT JONES, C. B., Inspector of Military Orthopedics, Army Medical Service. With an Introductory Note by Surgeon-General Sir Alfred Keogh, G.C.B., Director General, Army Medical Service. Illustrated. London, New York, Toronto, and Melbourne: Published for the British Red Cross Society by Cassell and Company, 1917.

ORTHOPEDIC surgery has been afforded a wide scope in the present war. By means of orthopedic centers established throughout the British Isles, men suffering from physical disabilities of their limbs are so treated that, as a rule, they are enabled to undertake useful employment. Thus habits of diligence are fostered, and indolent and often discontented individuals are conceived into busy and self-respecting members of society. This little book by Col. Robert Jones, the well-known British orthopedist, formulates rules for the application of orthopedic principles to the treatment of injuries received in war.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, etc. By Leading Members of the Medical Profession Throughout the World. Edited by H. R. M. LANDIS, M.D., Volume II. Twenty-seventh Series, 1917. Price, $2.00. Philadelphia and London: J. B. Lippincott Company.

IN this number of the Clinics appears an innovation in the nature of a section of Clinics by such well known clinicians as Henry A. Christian, Lewellys F. Barker, Edward Martin, Barton C. Hirst, and others. In addition the volume contains seventeen articles of the type usually found in this publication. Whether such publication of the reports of clinics is a valuable procedure is perhaps open to question, but certainly it is a popular one and the beginning thus made is very well done. Christian on Arthritis and Jones on Vertigo are especially interesting and instructive. Articles by Foote on Giovanni Lancisi and by Jelliffe on the Treatment of the Schizophrenic are particularly worthy of attention. It may be said unreservedly that this number is one of unusual value.

THE TREATMENT OF EMERGENCIES. By HUBLEY R. OWEN, M.D., Surgeon to the Philadelphia General Hospital; Assistant Surgeon to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases; Chief Surgeon of the Philadelphia Police and Fire Bureaus; Assistant Surgeon, Medical Reserve Corps, U. S. Navy. With 249 illustrations. Price, $2 net. Philadelphia and London: W. B. Saunders Company, 1917.

AS an outgrowth of the war there has been aroused an intense interest in first aid work and study on the part of the public. For a while this means seemed to be the one expression available among the laity of their desire to offer assistance to Uncle Sam in his fight.

Naturally such enthusiasm has hastened the publication of books on first aid to the injured, which might otherwise have been produced in a more leisurely fashion. Demand and supply certainly offer strong incentives, especially when backed up by the imminence of war.

Among this crop of first aid books comes one written by a surgeon, who for years has lectured to and instructed practically in first aid measures the policemen and firemen of Philadelphia, Pa. His book is an enlargement of these lectures. To one who has taught first aid, not only since it has become a fad, but through its droning, steady days, this little work is a volume of unmixed delight, relief, and satisfaction.

In the first place, it is written so concisely that not one word which is not required to elucidate the text has been employed. No space has been wasted on preliminaries, but the subject in hand is immediately taken up, and information, which is usually left in other works for the lecturer to supply, is found directly under the thumb. Secondly, no more anatomy and physiology is given than is absolutely necessary, for, as the author states, the book has been written primarily for the instructors of first aid to the injured, for police and fire surgeons, for ambulance surgeons, for resident physicians, for nurses, and for those laymen who wish to make a comprehensive study of the subject. This implies, of course, a previous study in anatomy and physiology. As one reads there comes the realization that the author has been born to command, and to instruct men in their conduct in times of emergency and stress.

It follows that the illustrations are all that may be desired, especially those portraying methods of bandaging, treatment for hemorrhage, and the machines used for resuscitation. One might venture to suggest that the illustrations of the Schaefer method of resuscitation could be made a little more clear, but the explanation in the text partially clears up this oversight. The reviewer has found that in teaching this method better results have been obtained by keeping the arms rigid, instead of working with bent elbows, as here shown.

The reviewer can best complete this review by resorting to the time-worn expression so often found in the reviews of long ago, that this book is a work which should be found on every bookshelf in the medical profession, and a truer statement has never been made.

THE PRACTICAL MEDICINE SERIES. Comprising ten volumes on the year's progress in medicine and surgery. Under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Volume VIII, Materia Medica and Therapeutics, edited by GEORGE F. BUTLER, Ph.G., A.M., M.D., Emeritus Professor of Therapeutics, Chicago College of Medicine and Surgery, Chicago, Ill. Preventive Medicine, Edited by WM. A. EVANS, M.S., M.D., LL.D., Ph.D., Professor of Preventive Medicine, Northwestern University Medical School. Series 1916. Price, $1.50. Chicago: The Year Book Publishers.

NATURALLY, since this book is written as a comprehensive review of a year's progress in these two subjects, it more than accomplishes its purpose. This volume is especially interesting in that it combines methods of treatment and means of the prevention of disease. Even an ice box for the shipping of water to needed quarters is shown by illustration as well as instructions for making the same.

Under personal hygiene is given a description of the clothes Dr. W. T. Grenfell advises for use in Arctic regions. One might wish that the same measures had been carried out with reference to the corresponding method of keeping cool in hot weather in the temperate zone. It is surprising how little is really written pertaining to the comfort and convenience of individuals required to meet conditions of unusual stress, even in the city of New York, during the intense heat. How many physicians or social workers are there who will ever reach the Arctic zone? But how many doctors and nurses are there who would like to present regulations as to clothing, hours of work, and definite knowledge of food to the public if the knowledge could be found in as condensed and well-written a form as this volume, which contains so much that is of absorbable value?

Altogether this special volume of the series does meet the requirements of the general practitioner in a very satisfactory manner. It brings together all the knowledge of a past year in a decisive style, and should save hours of reference research for hundreds of busy doctors.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-second Annual Meeting, Held at Pittsburgh, May 31 and June 1, 1917.

THE PRESIDENT, DR. FRANK FARROW SIMPSON OF PITTSBURGH, IN THE CHAIR.

An Histological Study of 50 Uteri Removed at Cesarean Section.—Dr. J. WHITRIDGE WILLIAMS of Baltimore presented a study of uterine contraction and retraction before the separation of the placenta; also a study of the mechanism of the separation of the placenta, the amount of decidua retained after separation of the placenta, the vascular changes at the placental site, and pointed out some of the indications for the removal of the uterus, notably ascending uterine infection. He likewise presented a study of the scar resulting from previous cesarean section.

Dr. EDWARD P. DAVIS of Philadelphia was of the opinion that once a cesarean section had been done, a spontaneous labor might happen in the same patient without any complications whatsoever; furthermore, a cesarean section, properly done not followed by infection, led to an absolutely sound uterus without connective tissue. As regards the separation of the placenta, clinically we might disregard those means immediately which lessened its bulk after the birth of the child, and that the clinical phenomena, aside from the histological findings of simple separation, varied greatly. As to infection and the removal of the body of the uterus, any one who had had considerable experience in cesarean section realized that the danger point was the uterine body in all doubtful and suspected cases. While it was difficult to say positively that a woman could not recover whose uterus was infected, he thought we would save far more lives in doubtful cases by hysterectomy than by leaving the uterus. He had never regretted removing the body of the uterus in all suspected cases, and he had regrets for not so doing.

Dr. EDWIN B. CRAGIN of New York City said that he would like to utter a word of caution as to the relative safety of a uterus on which cesarean section had been done, especially if the cesarean section was done for obstruction. As specialists all of us could appreciate the fact that if a uterus was properly sutured and the puerperium was without infection, that uterine wall would be relatively sound if the original operation was done for such a condition as placenta previa or for eclampsia; but if we were talking to general practitioners of the safety of the uterus that had gone through one cersarean section, we must always have that fact borne in mind, namely, if that cesarean section was first done for obstruction, there was a possibility that the puerperium was not absolutely free from infection. To allow that woman to work her way in labor in the second stage, with a scar following a puerperium, and not free from infection, was likely to expose her to the risk of a rupture.

Dr. CHARLES A. L. REED of Cincinnati stated that one point of practical interest was the time factor involved in the successful cicatrization of the cesareanized uterus. He had had one of those unique coincidences that sometimes would occur in practice, namely, he had had occasion to do myomectomy on two cases in which the injury to the uterus was done through cesarean section. In both he operated in the presence of an early pregnancy. The pregnancy was not interrupted. Cicatrization occurred very promptly.

Dr. JOHN O. POLAK of Brooklyn said that the point that impressed him in Dr. Williams' paper was the fact of 15 hysterectomies having been done following cesarean section. This statement was absolutely out of harmony with his experience as to the frequency of the necessity of this operation following cesarean section. Even with the 20 infections, there was a large proportion of these women who had had their uteri removed unnecessarily. It was likewise the experience of his colleagues in Brooklyn that they had not adopted the suggestion of Dr. William or of Dr. Davis of doing hysterectomy, but had treated these infected cases by the extraperitoneal method, and where they knew infection had existed from the history and by repeated examinations through the vulva, and had dealt with these cases on the modified principle of the suggestion of Sellheim.

Dr. HERMAN J. BOLDT of New York City said that while one swallow did not make a summer, he had had one opportunity of doing myomectomy during pregnancy. The woman was four months pregnant and showed symptoms of impending abortion. The myoma was enucleated because of the symptoms present. This woman made a good recovery and went on to term without any trouble whatever.

Dr. JOHN G. CLARK of Philadelphia said that in connection with the subject discussed by Dr. Williams, Dr. Goodell of Montreal brought out a rather interesting explanation a few years ago of the so-called myopathic hemorrhages which occurred in women of 35 and on. Dr. Goodell believed at that time that the subsequent reconstitution of the blood vessels in the uterus after the puerperium was due practically to the threading of new vessels into the old and their construction in that fashion. He believed that in the majority of women with myopathic hemorrhages at 40 and over we would find patency of the uterus up to the menopause, when there was a failure and bleeding because of successive rings. He had three or four specimens showing apparently one blood vessel within the other.

Dr. HIRAM N. VINEBERG of New York City stated that a puerperal uterus that was highly septicized could not be removed without causing a more severe infection. Dr. Williams had had 20 cases of infection, and the conditions at the time of operation were most favorable for the spread of infection, yet these uteri were all removed with recovery. The point he wished to emphasize was that these uteri could be removed with safety, and that there must be suitable cases in which the uterus could be removed and the patient's life saved thereby.

Dr. E. GUSTAV ZINKE of Cincinnati related one experience that he had had of a woman on whom he made two cesarean sections, the first time for an elongated cervix and placenta previa, both pronounced. She had a perfectly normal recovery. She became pregnant within two months after cesarean section and went near the end of term, when he was requested to attend her in confinement. He told her he would do so provided she would submit to another cesarean section, and he based his position entirely upon the fact that she had an elongated cervix. To overcome this obstacle necessarily meant a prolonged stage of labor, and not knowing exactly the character of the uterine scar, he did not wish to take any chances. She promptly submitted to another cesarean section, and it was performed exactly at the end of term as nearly as he could calculate and before the symptoms of her labor began after the cervix had been obliterated. To his surprise he found it was another case of placenta previa. The placenta was situated in the lower segment of the uterus, almost centrally implanted. Of the first scar hardly anything could be noticed. The first incision was made transversely near the fundus; the second he made longitudinally, and in both operations the abdominal incision was made above the umbilicus. She recovered from this operation very promptly.

Dr. J. RIDDLE GOFFE of New York City supposed that all physicians who had had experience in removing fibroid tumors had made observations in reference to the healing of the wound later, and it had appeared to endure subsequent pregnancies. He had operated upon three patients from whom he removed fibroid tumors and they had afterwards become pregnant. One recent case was one in which he operated for fibroid tumors at the fourth month of pregnancy. The tumors were removed, and the woman promptly miscarried. Since that time she had been pregnant twice and had borne children normally. The deliveries were perfectly normal.

Dr. WILLIAM E. STUDDIFORD of New York City stated that he had had in the past year and a half two experiences with rupture of the cesarean scar, the last one occurring about ten days ago. In both of these cases the woman went into labor prematurely. In the first case the condition was not recognized, and the prolonged pains led the attending physician to attempt further dilatation of the cervix by the use of the bag, with the result that the woman became infected, and at the time of operation the fetus and membranes were

within the abdomen. The uterus had retracted, and the woman died within 24 hours after operation.

Dr. George Gellhorn of St. Louis said that there were cases in which a very slight subfebrile temperature had been running for ten to fourteen days after cesarean section, suggesting the possibility that the wound had separated partially. He had had the opportunity of observing one woman who died about five weeks after cesarean section from a cause unconnected with the operation. She had a very slight temperature, not more than 99.2° or 99.4° for ten days. He was unable to find any cause for the rise in temperature. At autopsy he found the endometrial side of the incision had separated and gave a picture identical to that shown by Dr. Williams. It was very essential to pay attention to these slight rises of temperature and arrange for the management of the next labor accordingly.

Dr. John A. McGlinn of Philadelphia did not believe the dictum "once a cesarean section, always a cesarean section," was true by any means. Such a dictum was dangerous. It was simply a catch phrase which remained in the minds of many people who were not able to discriminate. It should be eradicated from the literature, because the general profession and even the public took hold of this catch phrase and would not allow cases to be cesareanized when they should be.

Dr. Franklin S. Newell of Boston said that his feeling about subsequent cesarean section was that we were never quite sure about the uterine scar. He had removed three scars at operation during the last winter. In two of them the patients ran a febrile course after the first operation. One of the scars left a mass of muscular tissue which ran through the middle of it, and he felt that if that patient went into labor she would have had a rupture. It seemed to him, that a two per cent. mortality following cesarean section in subsequent labors was too high. He did not believe that the mortality following cesarean section before labor was as high as two per cent. We should select these cases carefully, and he thought a woman ran less risk in having cesarean section done in a subsequent labor under proper conditions.

The Value of the Avoidance of Shock and Trauma in the Treatment of Eclampsia.—Dr. Edwin B. Cragin of New York City asked if we were treating eclampsia with better results today than ten or fifteen years ago, and if so, why? In the first series of 20,000 deliveries at the Sloane Hospital, New York, with 251 cases of eclampsia, the maternal mortality was 71, or 28.28 per cent. The fetal mortality was 151, or 16.15 per cent. In the last series of 15,774 deliveries, with 138 cases of eclampsia, the maternal mortality was 20, or 14.49 per cent. The fetal mortality, including stillbirths and those dying before mother left the hospital, was 62, or 44.92 per cent. The reduction in mortality had been brought about by avoiding shock and trauma; by avoiding chloroform; by preparing the cervix before delivery; by avoiding *accouchement forcé;* by treating the toxemia while preparing the cervix.

Dr. J. Whitridge Williams of Baltimore agreed with everything which Dr. Cragin said about sparing the patient every possible amount of shock during the time of delivery. Unlike Dr. Cragin, he had in the last few years resorted to bleeding which had had a good effect in a considerable number of cases of eclampsia, consequently it was almost a routine in his service now to bleed every woman with antepartum eclampsia, and when he did bleed he took away 750 to 800 c.c. In a certain proportion of cases that ended the misery. The woman had no more convulsions; her albuminuria fell; the nitrogenous constituents of the urine rose just as though she had not been bled, and such women occasionally went on for some weeks or even months and had a baby at term without further eclampsia.

Dr. Reuben Peterson of Ann Arbor, Mich., said that long ago he gave up the use of chloroform in the treatment of eclamptic women. The field of cesarean section, both vaginal and abdominal, had been limited for a number of reasons. In his experience, if you happened to deliver a woman there was less shock from abdominal cesarean section. Abdominal cesarean section was limited in a hospital that admitted all kinds of obstetric cases because there had been so many vaginal examinations made. If there was any chance for the woman to be septic one should work from below. One should try all the methods that had been indicated by Dr. Cragin, but should not resort to an abdominal cesarean section. His investigations of both abdominal cesarean section and vaginal cesarean section had shown conclusively that if a woman could be taken early in her eclampsia, both operations were remarkably successful in saving both the mother and the child. He had seen good results from bleeding, but had not obtained satisfactory results from the use of veratrum viride.

Dr. Brooke M. Anspach of Philadelphia asked Dr. Cragin and Dr. Williams in how many cases of eclampsia they found acetone and diacetic acid in the urine, and how they met the condition of acidosis? The reason he asked this question was because during the last year he had a woman to treat who developed very serious symptoms of a toxemia more than two weeks after delivery. She had three severe convulsions in one day. She showed remarkable improvement after the intravenous injection of a pint of a 2 per cent. solution of sodium bicarbonate, and she had another injection the next day and recovered.

Dr. Edward P. Davis of Philadelphia said that he would not deliver a woman in eclampsia and toxemia unless she showed signs of going into labor, then he would assist her with the least possible traumatism. His objection to the bag was the fact that its long-continued pressure sometimes exhausted these patients and led to the development of convulsions. Abdominal cesarean section was rarely indicated, and vaginal cesarean section still more rarely indicated. He had come to have a high regard for venesection in eclampsia if it was followed by the use of salt solution or sodium bicarbonate in the vein.

Dr. Harold C. Bailey of New York City stated that eclamptics were particularly prone to develop shock. *Accouchement forcé* had been discontinued in the Bellevue Hospital Service. In 1900, when he took systolic blood readings, several eclamptics were delivered by that method and in several instances he found there was a drop of 100 millimeters of mercury. He then made blood pressure readings following the use of veratrum viride, and in one instance in which the drug was pushed he found a drop of 140 millimeters of mercury, with the woman in profound shock. Since that time he had not previous to delivery used veratrum viride. As regards vaginal and abdominal cesarean section his views were in accord with those of Dr. Cragin.

Dr. E. Gustav Zinke of Cincinnati, Ohio, said that the principal cure for puerperal convulsions lay in prophylaxis during the pregnant state. Some of these cases would terminate fatally in spite of what we did, and when we had these women we were confronted by the question of whether we had a case which would yield to treatment, or whether it was one of those cases that would get well in spite of treatment and sometimes because of neglect. He was asked to see a woman in consultation about five weeks ago, with a pronounced case of albuminuria. She had edema almost up to the shoulders, and her urine was loaded with albumin. She was at the end of the eighth lunar month. He told them to give her gentle saline catharsis, a hot bath every day, and an absolute milk diet, and he said to the doctor that more than likely it would precipitate labor, and if it did it was much better for the patient. She was brought to the hospital three days after she had delivered herself spontaneously of a living child. The albumin slowly disappeared. The milk diet was kept up; she was given a hot bath every day. Her pulse was never very high. She was given veratrum viride. Ten days after labor she had her first convulsion, which left her with left-sided paralysis, and in spite of all that was done she had three other convulsions, and died in spite of all their efforts.

Dr. Cragin in closing said that in regard to diacetic acid and acetone in these cases of eclampsia, he recognized all types of cases, one where the liver was least involved, the other where the kidney was more involved, and in a case where the liver was the organ more involved, we were more apt to get acetone and diacetic acid, and there soda had proved valuable in his hands.

Symposium on Radium Therapy — Methods and Results of Radium Treatment of Uterine Hemorrhage Due to Other Causes Than Malignancy. — Dr. Howard A. Kelly of Baltimore, in behalf of himself and Dr.

Curtis F. Burnham presented a report on 100 cases of uterine hemorrhages treated with radium and radium emanation. He pointed out how frequently doctors were consulted for this troublesome symptom and how weak the therapeutic arm had been, in that so many patients were subjected to a hysterectomy when curettage failed. Radium therapy here was as simple and as safe as a dilatation of the cervix, and consisted in nothing more than introducing a uterine sound with a hollow tip containing 500 millecuries of emanation and applying it successively to some eight different points in the uterus, fifteen minutes at each point. This practically always cut short the menstrual function and so simply obviated the need for a hysterectomy. In young women, as shown by several cases reported, the menstruation could sometimes be modified without even suspending it. In one case pregnancy and delivery of a healthy child followed the treatment. Seven of the 100 cases cited had heart disease, 2 epilepsy, 2 insanity, others Bright's disease and tuberculosis, manifestly bad risks for hysterectomy. No serious sequelæ followed the radium treatment. Also practically in all cases of fibroid tumors, radium had checked the monthly flow completely when desired. In young women it had been possible in some instances to cause the tumor to disappear without stopping menstruation permanently.

Radium in the Treatment of Uterine Hemorrhage and Fibroid Tumors.—Dr. C. JEFF MILLER of New Orleans stated that while it had been shown that the early extravagant claims as to the curative powers of radium in cancerous lesions had not been verified by subsequent analysis of case reports, it had developed that its effect in the treatment of uterine bleeding from various causes was almost that of a specific. Its most striking effect was its certain control of uterine bleeding due to the metropathies, or aberrant ovarium function. Aggravated cases of the menopause, usually relieved by hysterectomy, could be controlled by a single application of radium. Similar results were obtained in bleeding complicating fibroids of the uterus and certain types of fibroids might disappear or markedly shrink. Radium would not supersede surgery in the treatment of fibroids. Large growths giving rise to pressure symptoms, or presenting evidences of degeneration as well as submucous tumors should be treated surgically if operation was not contraindicated. When desirable to preserve the function of the generative organs in young women surgery should be considered the more conservative procedure since it permitted myomectomy. Its effect in controlling bleeding associated with chronic metritis and polypoid endometritis was equally satisfactory and when the dosage and screening were carefully measured it might be used as a last resort in excessive bleeding in young girls without causing cessation of the menses. Itching associated with kraurosis of the vulva, as well as pruritus, could often be promptly allayed by radium. Statistics to show the primary and ultimate results were necessary to prove its real therapeutic value. Results of its use during a period of three years showed that the primary results in controlling uterine bleeding were nearly 100 per cent., the ultimate results varying according to the times and number of exposures.

Radiotherapy in Uterine Hemorrhage of Benign Origin.—Dr. JOHN G. CLARK of Philadelphia said that in cases of hemorrhage of the uterus of benign origin, such as that from small myomata or myopathic change, particularly in women over 38 years of age, radium in small doses was one of the most effective remedies, relieving practically all of the cases from even the slight hazard to a major surgical operation. The hemorrhages in such cases stopped promptly and with rare exceptions permanently without untoward effects incident to the use of radium. Analysis of cases according to age indicated that those near the menopause responded best. Cases in former years, in which even repeated curettages failed to alleviate the hemorrhage, were promptly terminated after the application of 50 milligrams of radium for twenty-four hours. In over 100 cases there had been but one failure to relieve the hemorrhagic symptoms in these cases.

Radium in Uterine Cancer.—Dr. HAROLD C. BAILEY of New York City, in his paper discussed the present status of radium in the treatment of uterine cancer, followed by a detailed description of the technique used at the Memorial Hospital in 1915-16, and gave the account of a new method or adaptation for filtering the rays which had been gradually developed and had been adopted as the regular technique since January 1, 1917. The platinum applicators holding large amounts of radium emanation were placed in an iron capsule containing mercury. This mercury "bomb" offered efficient protection to the normal tissues and permitted of the entire lower part of the pelvis being swept with a sufficient dose in a period of usually not more than four or five hours. In addition, heavy applications were made over the lower part of the abdomen in three areas and directed towards the upper part of the pelvis. In this manner, from the standpoint of the amount of radiation, three or four times the dose possible with the ordinary technique could be directed into the pelvis and without subsequent irritation. He gave a general description of 125 cases treated since January, 1915, the accessory treatments, the amounts of radium used and the results to date.

Dr. FRANCIS CARTER WOOD of New York City said that he had had but little personal experience with the use of radium in the treatment of uterine hemorrhage. Those cases he had seen had suggested the necessity of an accurate preliminary diagnosis of the condition of the endometrium by the thorough microscopic study of curettings removed with care so as to obtain as large fragments as possible and promptly preserved. Without such precautions in obtaining the material, a satisfactory study was often impossible. He had seen a few cases treated in which the radium did not cause a cessation of the hemorrhage until such doses had been administered as to cause atrophy of the ovaries. As to the treatment of fibroids, he felt from his pathological experience that only a moderate percentage could be properly handled by radiation. It must be remembered that after extensive radiation hysterectomy, should it prove necessary, might be very difficult owing to the cartilaginous fibrosis of the parametria.

Dr. HERMAN J. BOLDT of New York City said that he wished to refer to hemorrhages from benign causes. While radium had certain advantages, he had failed to hear the final results from its use. Similar results might be obtained from the proper intrauterine application of chlorid of zinc. The advantage of radium was that less applications might be necessary. One might obtain a result after one or two treatments which might require a dozen treatments by chlorid of zinc. Radium might cause less pain than chlorid of zinc, but the proper application of a 50 per cent. solution of chlorid of zinc in the form of an intrauterine tamponade, would bring about a result equally as good as that by radium so far as the cessation of hemorrhage was concerned.

Dr. ERNEST C. SAMUEL of New Orleans, La., stated that when the hemoglobin was low he had found that a smaller dosage of radium spread over a longer period of time produced less toxic symptoms than a large dose over a shorter length of time. He was glad to have heard a statement by one gentleman that he had found only 2 or 3 per cent. of toxic symptoms as the result of radium applications. That had not been his experience. Almost 90 per cent. of patients that he made intrauterine applications to or applications around the cervix developed a distressing nausea and vomiting and some elevation of temperature.

Dr. HENRY SCHMITZ of Chicago believed that the radiotherapist who used small amounts of radium obtained as good results as the man who used larger amounts. In benign conditions he used less milligrams of radium, and the physical condition of the patients was much better than we found it in malignant conditions. The malignant cases very frequently showed advanced cachexia and anemia. Their resistance was materially lowered, and in such cases it was necessary to use larger amounts of radium rays than in non-malignant conditions.

Dr. WILLIAM P. GRAVES of Boston said that he had noted one thing which had not been mentioned in this symposium and that was that the successful reaction of the cancer cells to radium depended considerably upon the histological structures of the cancer. Cancers that were purely squamous in type, starting from the

portiovaginalis, were much more favorable to treatment. Those cases which originated in the endocervix, that was, adenocarcinoma of the cervix, did not respond in the same way.

Etiological Study of Vulvar Carcinoma.—Dr. FREDERICK J. TAUSSIG of St. Louis, Mo., stated the 15 cases upon which this paper was based were observed, with but one exception, at the Barnard Free Skin and Cancer Hospital, in the services of Dr. Gellhorn and himself. Eight of their patients received deep *x*-ray treatment, four of them with the Coolidge tube, but in none was there more than a very temporary improvement. They had come to the opinion that the *x*-ray could only be considered as an auxiliary to surgical measures in vulvar cancer. They had no radium to use, but it was difficult to see how its results could have been any better in view of the early and extensive involvement of the lymphatic system in these patients. There remained, therefore, only radical surgical removal as a therapeutic agent. It was difficult to work out a definite style of operation for a condition that was encountered so rarely as that of cancer of the vulva. However, through various untoward results, such as frequent glandular recurrences in the femoral ring, extensive postoperative necrosis of the vulva, inguinal infections, local implantation metastases, he had recently adopted the following two-stage operation technique: (1) Dissection of the entire superficial and deep inguinal and femoral lymphatic chain by the method of Basset. As seen this method consisted of an incision opening the entire inguinal canal and subperitoneal spaces in the iliac fossa superior to the external iliac vessels. After this chain had been lifted out, attached to the round ligament, the femoral glands were dissected out around the saphenous and femoral vessels. Now came the point of special value. Poupart's ligament was cut across over the femoral ring and the deep gland situated beneath it freed with its attendant fat and lymph vessels. The round ligament was then tied off at its entrance into the peritoneal cavity, and the entire lymph gland mass excised. The deep epigrastric vessels had to be ligated close to their point of origin in order to permit of a clean dissection. The femoral ring was closed by suturing the internal oblique to the femoral fascia, Poupart's ligament was then sutured over this, and a small drain placed in the deeper subperitoneal space. In all instances both sides should be cleaned out by a separate incision in this radical manner. The primary tumor of the vulva was kept away from the operative field in the inguinal region during and after this first operation. Only a sterilizing dose with the Coolidge tube and ordinary antiseptic treatment were employed to keep it clean. (2) Two weeks later the inguinal wounds had healed usually by first intention. He then proceeded to an excision of the vulva, using neither scalpel nor scissors, but only the cautery knife. No attempt was made afterwards to close the wound entirely by a dissection of flaps. Instead, a half dozen silk work gut sutures alone were used to approximate the skin edges. Thus a considerable surface was left denuded. No dressing was kept on the wound after the patient was back in bed. Under the open air treatment, with the occasional assistance of dry heat and the frequent irrigation of the vulvar wound with Dakin's solution, he had obtained rapid granulation, and none of the necrosis and infection that otherwise in his experience had been uniformly associated with these extensive vulvar excisions in old women. He believed this method of operation had distinct advantages.

Adenomyoma of the Rectovaginal Septum.—Dr. THOMAS S. CULLEN of Baltimore said that these growths were usually situated in the vaginal vault directly behind the cervix. They soon became adherent to the rectum and later might spread out into the broad ligaments. Histologically they consisted of nonstriped muscle and fibrous tissue. Scattered through the growth were islands of uterine mucosa. He referred briefly to his previous papers on the subject and then reported two cases. The first tumor was small and situated in the usual position. The second case was unique. Posterior to the cervix several small polypi projected into the vagina. On histological examination they were found to be typical adenomyomata covered by vaginal mucosa. Both broad ligaments were board like and at each period the patient had pain in both renal regions. At operation both broad ligaments were also found involved by the adenomyoma. The ureters were markedly dilated in the pelvis, each being one centimeter in diameter. Where they passed through the broad ligaments they were markedly narrowed by the adenomyomatous growth. Near the bladder they were of nearly normal caliber. The pain in the kidney regions at the periods was undoubtedly due to the increased compression on the ureters by the adenomyomatous tissue that naturally swelled at the time of menstruation. The ureters were liberated, the uterus with a portion of the vagina was removed. A portion of the growth was left attached to the rectum and in both broad ligaments. The patient was later treated with radium.

Gastrointestinal Conditions in Women.—Dr. CHARLES A. L. REED of Cincinnati, Ohio, stated that the chief distortions of etiological and pathological significance to which he invited attention had occurred under his observation in approximately 3,000 cases during the last eleven years. They were mentioned in their relative order of frequency as confirmed by physical examination, *x*-ray records and surgical exploration. The colon, ptosic, retardatively angulated, sometimes redundant, occasionally adherent, was the most frequently observed seat of distortion. Next was the cecum, dilated, flabby, hypermobile, often adherent, but more frequently covered with highly organized exudate. The ileum was often ptosic, angulated near its cecal end, dilated back of the angulation, and the seat of marked stasis. Adhesions of the terminal ileum were of frequent occurrence, while Lane's kink was occasionally encountered. He recently had four in succession. The ileocecal valve was sometimes incompetent. The duodenum, always dilated in the presence of constrictions or angulations at the terminal ileum, was also frequently enveloped in a highly organized exudate and frequently adherent. The sigmoid or pelvic colon was often redundant and was sometimes the seat of constrictive narrowing at its juncture with the descending colon. The vermiform appendix was generally normal, but was sometimes either adherent, atrophied or distended, only occasionally being the seat of active mischief. Chronic intussusception with adhesions of invaginated surface had been encountered. Diverticula and neoplasms both benign and malignant of the intestinal wall had been observed. The fat, often really lipomatous omentum, often found in these cases had a demonstrated etiological relationship to displacement of the colon and stomach. The stomach was generally found vertical to the left side, often of the fishhook type, sometimes extremely ptosic, and not infrequently the seat of adhesions to the mesocolon. Pyloric insufficiency occasionally with active ulceration of the pylorus, or duodenum, or both, was encountered. Another condition of great importance, but really secondary to the distortions mentioned, was that of general visceral cyanosis in which the veins, more especially of the mesocolon and the mesentery, were greatly dilated and filled with very dark blood, showing circulatory stasis, with resulting dangerous deoxygenation of the considerable quantity of blood thus impounded. It was to be understood that these conditions were rarely, if ever, found singly, just as it would be obviously improbable that all of them should exist in the same case at the same time. It was also to be remembered that certain of these conditions, as, for instance, a more or less marked ptosis of the colon, or certain adhesions, or even marked redundancies, might exist without producing symptoms. It was only when marked symptoms did exist, and when they were logically and obviously referable to the conditions enumerated, or to any of them, that the latter were to be recognized and treated as pathological within themselves and etiological with reference to secondary or other sequential phenomena. In any event, the conditions enumerated were sufficient to show that there is abundant pathology in the cases under consideration. As to treatment, it was essential to remember that the practical problem, so far as it is presented in the course of gynecological practice, was distinctly three fold, namely, the intestinal condition, the constitutional state, and the gynecologic sequelæ or complications. As to the intestinal condition, it should be carefully determined in the routine diagnosis of

every case; it should be recognized as initial pathology, and should be treated in accordance with its specific indications. This did not mean that every case should be remanded for operation. Other methods of treatment should be recognized as available in certain of the milder cases in which the ptosis was not pronounced or of long standing, or in which the constitutional conditions were not yet severe. The constipation, or its sequel, demanded first attention. Mild solvent laxatives and a diet less in protein and rich in cellulose, with intestinal antisepsis, associated with alkaline lavage of the large bowel, were indicated. The most important treatment of this class of cases was prolonged rest in bed with passive exercise and forced nutrition with a balanced dietary. If the intestinal distortions were marked, and especially if they were associated with adhesions, surgical intervention was demanded. Surgery should always be adapted to the specific indication presented, and it should always be applied on the principle of the minimum of surgery with which to meet the object in view. Acting on this principle, he had had occasion to break up adhesions, to relieve angulations, to remove redundancies, and to extirpate functionally dead segments of the intestine. The procedures involved had embraced appendectomy, appendicostomy, cecostomy, parietal implantation of the colon, resection of redundant transverse colons, resection of redundant sigmoids, removal of the right colon with end-to-end anastomosis, ileosigmoidoscopy, with colon exclusion, and ileo-sigmoidoscopy with secondary colonectomy. In certain cases shortening of the mesocolon and the mesentery was done by peritoneal plication.

Symposium on the Relation of the Glands of Internal Secretion to Gynecology and Obstetrics.—Dr. ROBERT T. FRANK of New York City stated that the reason for concentrating mainly upon the physiological aspect was twofold. First, in this subject, even more than in most others, a solid experimental foundation was essential; second, a mere experience meeting would be of little lasting value, and, at least part of the clinical data properly belonged to the discussion which was to follow the reading of the papers. Consequently it was considered advisable to assemble in easily accessible form facts, some new, others scattered in the literature, which were most important in the further study of the subject and which promised later to prove most valuable when applied to practical gynecology and obstetrics. It proved impossible to enlist authors to present the clinical aspects of such important glands as the thyroid and adrenals. In order to introduce the discussion, it had been deemed advisable to present in most condensed form the various outlines of the contents of the referats. The authors present would do this for their own papers, the committee undertaking the presentation for the absentees.

The Relation of the Pituitary Gland to the Female Generative Organs; from the Experimental and Clinical Aspects.—Dr. EMIL GOETSCH of Baltimore drew the following conclusions: (1) There is a close interrelationship in function between the pituitary and sex glands, a fact supported by abundant experimental evidence and by numerous observations on pituitary disturbances in the human subject. (2) Overfunction of the pituitary anterior lobe is associated with overactivity of the sex glands. (3) Deficiency of pituitary secretion in the individual is followed by underdevelopment and genital aplasia in the young and by sexual inactivity and retrogression in the adult. (4) Primary alterations in the function of the sex glands, as in pregnancy and after castration, are followed by pituitary hypertrophy and hyperplasia. (5) The specific action of posterior lobe extract (pituitrin, pituitary liquid) upon the smooth musculature of the uterus and bowel had led to the wide usage of this drug in obstetrical practice and in the treatment of intestinal paresis following abdominal and pelvic operations. (6) The administration of pituitary extracts was of distinct benefit in clinical states of pituitary underfunction.

The Pineal Gland Influence upon Growth and Differentiation with Particular Reference to Its Influence upon Prenatal Development.—Dr. CAREY PRATT MCCORD of Detroit, Mich., said that from the lack of unanimity in the literature any conclusions as to the details of pineal gland function must be made flexible rather than dogmatic. A survey of available data led to the following summary as representing the present status of the pineal gland as an organ of internal secretion: (1) A clinical syndrome was to be associated with disturbances of the functions of the pineal gland. Because of the involution of the pineal at puberty the constitutional manifestations of pineal pathology appeared to be confined to prepubertal years. The essential characteristics (apart from pressure and neighborhood manifestations) were (a) early sexual development evidenced in the enlarged genitalia, pubic hair, general body hair, early change in voice; (b) precocious mental development, manifested in maturity of thought and speech; (c) general overgrowth of body to the extent that a child of 6 or 7 years might have the appearance of a child near puberty. (2) The experimental extirpation of the pineal gland was surgically possible. The gland was not essential for the maintenance of life. The early symptoms following pinealectomy were attributable to the severe brain injury. No changes attended the removal of the gland in adult animals. As to the effects of pinealectomy in young animals, Sarteschi, Foa, and Horrax respectively stated that the removal of the gland led to precocity of development. Exner and Boese, and Dandy reported no changes after pinealectomy. (3) The administration of pineal substance to young mammals was reported to hasten growth and sexual maturity. In unicellular organisms (paramœcia) pineal extracts increased the rate of reproduction to more than double that of controls. In larval forms (ranidæ) both growth and differentiation were hastened as a result of pineal feeding. (4) The inference was allowable that the pineal gland was an organ of internal secretion whose functions, however, were of minor significance in the general activities of the endocrinous system.

The Physiological and Pathological Importance of the Parathyroid Gland from the Experimental Aspect.—Dr. CARL VOEGTLIN of Washington, D. C., drew the following conclusions: (1) The parathyroid gland has a definite physiological function which is still incompletely understood. (2) The presence of a minimum of parathyroid tissue in the body is essential for life and the continuation of normal metabolism. (3) Parathyroid insufficiency seems to be characterized by an increased irritability of the nervous system to the galvanic current, which may be due to the withdrawal of soluble calcium salts from the blood and tissues. Parathyroid insufficiency leads to an alkalosis which is converted into an acidosis as a result of active tetany. Definite metabolic changes take place in animals after complete parathyroidectomy. (4) Pregnancy puts an extra strain on the functions of the parathyroid, as evidenced by the appearance of tetany during this period in partially parathyroidectomized animals. (5) Tetany has been observed during lactation in animals with parathyroid insufficiency. Interruption of lactation was followed by recovery. (6) The offspring of partially parathyroidectomized animals exhibit a marked increase in nerve irritability. (7) An intravenous injection of soluble calcium, or strontium salts, or hydrochloric acid almost instantly removes the symptoms of tetany. However, tetany may reappear after this treatment, and the life of such animals cannot be saved by the continued administration of calcium. The injection of parathyroid extract seems to have a temporary curative effect on tetany animals. Isotransplantation of parathyroid into animals with parathyroid insufficiency is usually successful. The spontaneous recovery from tetany in experimental animals is probably due to changes in their metabolism (acidosis) caused by the hyperacidity of the skeletal muscles during tetany. (8) The experimental facts do not support the theory that eclampsia is due to hypoparathyroidism. (9) A condition which might justly be termed hyperparathyroidism is unknown at the present time.

The Relation of the Parathyroid System to the Female Genital Apparatus.—Dr. EUGENE H. POOL of New York City drew the following conclusions: (1) No direct relationship has been established between the parathyroids and the female sex organs; no morphological changes in the parathyroids have been noted during pregnancy; yet apparently there is a connection between the parathyroids and the sex processes in the female. (2) Tetany, the clinical evidence of insufficient

parathyroid function, is somewhat prone to occur in menstruating, pregnant and puerperal women, as well as patients suffering from gynecological diseases, or who have undergone gynecological operations. (3) The cause of maternal tetany is now referred to parathyroid insufficiency. (4) The function of the parathyroids is apparently closely connected with calcium. (5) There is reason to believe that maternal tetany and lactation tetany are associated with calcium deficiency. (6) Latent tetany, or a subtetanic condition, is much more common in pregnant and puerperal women than is usually assumed. (7) Tetany in newborn infants, the offspring of tetanic mothers, is usually fatal within a short time after birth. (8) In the treatment of maternal tetany the administration of calcium in large doses is followed by beneficial results in the great majority of the cases.

The Thyroid Gland in Relation to Gynecology and Obstetrics. — Dr. DAVID MARINE of Cleveland Ohio, said that in summarizing it might be stated that there was evidence in man of a thyroid sex gland interrelation recognizable in the female in association with the development of secondary sexual characters, with the menstruation and with pregnancy and also in the male at puberty, but to a very slight degree. The meager evidence available would tend to indicate that the interstitial cells of the ovary and perhaps, also, the adrenal cortex played a major role in this relation in the female, as certainly the cells of Leydig did in the male. The thyroid enlargement was of the nature of a work hypertrophy to stimulate metabolism identical in appearance, and so far as they knew, different only in degree from that seen in simple goiter. Both of these reactions could be controlled and prevented either indirectly by giving iodine or directly by giving the iodine containing hormone in physiological doses.

The Possible Bearing of the Thymus Gland upon the Female Genital Tract.—Dr. ALVIN M. PAPPENHEIMER of New York City stated that there were many points of interest in connection with the thymus which he had not attempted to discuss, but it was doubtful whether even the most detailed scrutiny of the enormous literature would lead us to more satisfactory conclusions. The fundamental problems of thymus physiology remained unsolved, and the established facts, which concerned chiefly the normal and abnormal structure of the gland, were not such as lent themselves to clinical application.

The Endocrine Function of the Pancreas and Its Relation to the Sex Life of Women.—Dr. A. J. CARLSON of Chicago drew the following conclusions: (1) All evidence supports the view that some substance or hormone secreted by the Islands of Langerhans into the blood is necessary for utilization of sugar by the tissues. This function is specific for the pancreas. Other endocrine organs may influence sugar metabolism in a superficial way by altering the sugar mobilization (adrenals, thyroid), or by increasing or decreasing the rate of oxidation in the body in general. The rest of the endocrine glands cannot maintain the power of the tissues to oxidize sugar in the absence of the pancreas, and the hypo or hyperactivity of other endocrine glands do not produce actual diabetes in the presence of a normal pancreas. (2) While the failure of the tissues to use sugar in the absence of the pancreas is the central and definitely established fact, there are probably other primary defects involved in the development of acidosis, lipemia, increased metabolism, lowered resistance to infections, etc. (3) All the evidence points to the view that true diabetes mellitus in man is primarily the result of pancreatic deficiency (islets). (4) There is, at present, no organotherapy of diabetes, experimental, or clinical. (5) There is, at present, no evidence of any specific relations of the endocrine functions of the pancreas to the gonads, male or female, or to menstruation, pregnancy, and lactation. Absolute diabetes, induced after conception, leads to death of the fetus. Absolute diabetes probably renders conception impossible. Partial diabetes under careful dietary control permits of normal sex life of women (menstruation, normal pregnancy, normal child, lactation), and pregnancy under such conditions does not aggravate the diabetes. But in the absence of such dietary control the condition of pregnancy aggravates the diabetes in the mother, and uncontrolled diabetes in the mother is extremely injurious to the fetus. There is some evidence that in late stages of pregnancy the fetal pancreas may function for the mother.

The Experimental and Clinical Evidence as to the Influence Exerted by the Adrenal Bodies upon the Genital System.—Dr. SWALE VINCENT of Winnipeg, Manitoba, read this paper, of which the following is a summary: (1) What we call the adrenal body represents the anatomical association of two elements, each of which is derived from a separate and independent system. The adrenal proper, or cortex, is a part of the cortical or interrenal system. The medulla is simply an accumulation of chromophil cells of the same nature histologically, chemically, and pharmacodynamically, as similar masses of cells in other parts of the body. (2) There is no clear evidence that these two systems are functionally related. (3) The adrenal medulla, as well as the chromophil tissue generally, is developed from the sympathetic nervous system. Its duty seems to be to facilitate the functions of this system in certain physiological emergencies. (4) The adrenal cortex (as well as the accessory cortical adrenals) is developed from the germ epithelium, and the evidence is now strongly in favor of the view that it has certain important functions in connection with the development and growth of the sex organs. (5) There is a considerable amount of clinical evidence that tumors of the adrenal cortex are frequently associated with sex abnormalities. (6) The clinical evidence also favors the view that when cortical tumors occur in the female an accentuation of male secondary sexual characteristics develops, and simultaneously a hypoplastic condition of the internal generative organs supervenes. (7) The additional evidence as to a connection between adrenal cortex and the sexual organs is furnished by the enlargement of the cortex during breeding and pregnancy. (8) Feeding young animals with adrenal gland substance seems to stimulate the growth of the testes. (9) It is possible that a final solution of the problem will only be arrived at when the more general problem of the relationships between the ductless glands shall have been solved.

The Relation of the Ovary to the Uterus and the Mammary Gland from the Experimental Aspect.—Dr. LEO LOEB of St. Louis, Mo., drew the following conclusions: (1) The ovary is a complex gland, of which the most important constituents are follicles in various stages of growth and atresia, and corpora lutea. In addition we find in some species interstitial gland and some embryonic structures developing parthenogenetically from eggs. (2) Cyclical changes occur both in the ovary and secondarily in the uterus and mammary glands. (3) The primary cyclical changes in the ovary are in sequence; follicle ripening, ovulation, corpus luteum formation. In some species ovulation is accompanied by degeneration of all but the smallest follicles. (4) An elaborate self-regulating mechanism controls ovulation. Normally the corpus luteum inhibits ovulation. During pregnancy the life of the corpus luteum is prolonged. Experimentally ovulation can be influenced at will, accelerated by excising all corpora lutea, or retarded by producing artificial deciduomata. The retarding action of the corpus luteum is chemical, not mechanical. (5) The corpus luteum has a sensitizing action upon the uterus. This action can be analyzed by experimental methods. If the uterus is incised or mechanically stimulated at the time during which the corpus luteum is elaborating this growth substance, maternal placenta (deciduoma) is formed. The mechanical stimuli, therefore, assume in this respect the function which the ovum exerts under normal conditions. The form of growth response of each species is characteristic. The localization of sensitization varies in different species, being limited to the uterus in rabbits and guinea pigs, but distributed more widely in the human female. No specificity exists in the sensitizing substance given off by the corpus luteum as far as different individuals of the same species are concerned. The life period of experimental deciduomata is short except in pregnancy, during which their persistence is prolonged. (6) Corresponding to and dependent upon the cyclical ovarian changes, uterine cyclical changes occur. The cycle consists of heat, growth, with associated glandular ativity, regression, and interval. Heat probably is due to maturation of the follicles and dependent

upon the absence of the corpora lutea; growth activity is the result of corpus luteum secretions; regression marks the cessation of corpus luteum secretion, which is followed in the interval by a condition of rest. Pregnancy causing a persistence of the corpus luteum is characterized by an accentuation, but not a prolongation of the active phase, and an inhibition of the uterine cyclical changes throughout gestation. (7) While it is possible to produce experimentally during pregnancy a new ovarian cycle, through excision of the corpora lutea, such a new ovarian cycle is not followed by a new uterine cycle. During pregnancy a mechanism is at work preventing the uterine mucosa from responding to the stimuli given off by various ovarian structures. (8) It follows from conclusions 4, 5, and 6 that the corpus luteum subserves at least two functions, inhibiting ovulation and producing a substance which causes growth in the uterus. (9) The ovary shows other noncyclical functions. It has a trophic influence on the genitals and either primarily or secondarily determines the development of the secondary sexual characters. (10) The ovary likewise controls the development of the mammary glands. It exerts a trophic influence on this organ and determines its normal cycle. During heat and subsequent to ovulation proliferated changes occur; these cease while the corpus luteum develops and functionates. (11) The incidence of breast cancer in mice is greatly reduced by castration.

Transplantation and Retention of Ovarian Tissue after Hysterectomy.—Dr. WILLIAM P. GRAVES of Boston drew the following conclusions: (1) Specific surgical menopause symptoms consist chiefly of vasomotor disturbances in the form of hot flushes. (2) Theoretically, vasomotor changes of the artificial menopause are due to a break in the uteroovarian functional harmony, by which the physiological balance of the glands of internal secretion is upset with consequent dysfunctional activity. (3) After extirpation of the uterus, vasomotor disturbance ensues with approximately equal frequency, whether the ovaries be retained *in situ*, totally ablated, or transplanted. (4) Retention of ovarian tissue after hysterectomy is of little or no physiological value and may be productive of serious harm to the patient.

The Preparation and Standardization of Ovarian and Placental Extracts.—Dr. WILLIAM H. MORLEY of Detroit, Mich., drew the following conclusions: (1) A more uniform method of preparing extracts must be instituted. (2) Some method for the standardization of these extracts must be discovered, in order to facilitate the comparison of the results of the different laboratory workers and clinicians. (3) Many results obtained in the laboratory or in the clinic are due to the faulty preparation of extracts. (4) The isolation of the active principle of the ovary and the placenta will clear up many, if not all, of these mooted points.

The Placenta Regarded as a Gland of Internal Secretion.—Dr. ROBERT T. FRANK of New York City presented this communication, of which the following is a summary: (1) The experimental work of the last decade proves that Halban was correct in ascribing to the placenta an action upon the uterus and breasts. (2) Placental extracts (mainly the lipoid fraction) rapidly induce hyperplasia of the uterus and breast, gland tissue and nipples), in castrated or in noncastrated animals. (3) The chemical substance which induces these changes is thermostabile, very resistant to strong alkalies and acids, and completely soluble in 95 per cent. alcohol. (4) The substance appears identical in its physical, chemical, and biological properties with a similar substance obtained from the corpus luteum. (5) The substance can exert its influence in the absence of the thyroids, adrenals, pancreas, or in the absence of thyroid and adrenals combined. (6) In view of the apparent identity of corpus luteum and placental substance, the question arises whether the placenta acts merely as a storage reservoir for corpus luteum secretion during the latter half of pregnancy, or whether the placenta elaborates a hormone of its own.

Relation of the Sex Glands to Metabolism.—Dr. JOHN R. MURLIN and Dr. HAROLD C. BAILEY of New York City drew the following conclusions: Our results uphold the work of Loewy and Richter so far as the reduction in metabolism after castration is concerned. Removal of the ovaries of our dogs was followd by an increase in weight in both and a lowering of the metabolism in from 12 to 17 per cent., and in the other from 6 to 14 per cent. We feel that indirect action has a bearing on this reduction, and we do not believe that the indications point decisively to the loss of a specific stimulus from the ovary affecting the oxidative processes of the cells. To throw more light on this complex subject further experiments with animals are necessary.

Dr. J. WHITRIDGE WILLIAMS of Baltimore said that every one who was dealing with obstetrics knew what pituitrin was and what the extract did. In the discovery of the physiological action of the posterior lobe of this gland we had a most powerful therapeutic agent, one which was doing a great deal of good and, at the same time, doing a great deal of harm. The active principles had not been thoroughly worked out, but there was a good deal to be learned about it. The active principle of the posterior lobe, the pituitary body, and active principle of ergot were closely related, and it was likely in the use of pituitary extract we might go through the same cycle which we went through with the use of ergot. The injection of a cubic centimeter of any of the ordinary pituitary extracts in many cases had a marvelous effect. Within three minutes after injection of this drug the uterus, which previously had been acting in a very sluggish way, took on intense activity, and often labor would be brought to a standstill within the next few minutes. About the thyroid, his practical experience with pregnancy, complicated by goiters of various kinds, had shown him that the condition could be in great part disregarded.

Dr. GEORGE GELLHORN of St. Louis, Mo., had observed great improvement in two cases of kraurosis vulvæ. In one there had been permanent relief after feeding the patient ovarian extract; another one was temporarily improved after injecting the extract. Neither suggestion nor deception was permitted to enter. The sole criterion was a change from the dry, glistening, unyielding tissue to a soft, moist, and pinkish mucosa which bore no evidence of scratching. If in two cases of senile osteomalacia the same therapy led to a temporary restoration of locomotion, it was hard to explain it on the ground of suggestion.

Dr. JOHN G. CLARK of Philadelphia said that with regard to Dr. Goetsch's paper he could not help but feel that the preservation of normal ovarian tissue was of very vital value in younger women. He made this statement based upon a long series of cases. If there was any one point that was definitely conclusive it was the retention of ovaries or an ovary, regardless of whether the uterus was present or not. It was of vital importance to a young woman. He had noticed this in following up his cases, and it had largely determined him along the lines of a more radical policy so far as inflammatory cases were concerned. He had observed in the younger women in the ward that where ovaries suggestively diseased were preserved these patients did not have a satisfactory postoperative convalescence. A large proportion of them subsequently suffered pain and distress free from pathology. In fibroid cases in young women, where the ovaries were normal, he saw definitely better results than under the older methods where the ovaries were removed.

Dr. FRANCIS CARTER WOOD of New York City stated that he had tried the Beatson operation experimentally and the influence of the removal of the ovaries on carcinoma of the breast. This operation produced a temporary effect, which was no doubt due to the removal of the secreting substance of the ovary or due to nutritional and vascular conditions. He took primary tumors in mice and gave large injections of corpus luteum and *x*-rayed a number of the mice and no effect was produced, so that this substance when injected into an animal caused hypertrophy of the breast itself and growth of the epithelium. The cancer tissue lost its power to respond to this peculiar substance.

Dr. C. C. GUTHRIE of Pittsburgh said that in reference to Dr. Graves' work on the transplantation of ovaries, his interest was aroused years ago when he conducted experiments in laboratory fashion on the transplantation of ovarian tissue. In the later nineties or shortly thereafter Dr. Robert T. Morris of New York reported the birth of a child in a woman whose ovaries had been removed and replaced by other ovaries. So far as he knew, this was the first authentic account of

the reproductive function after the transplantation of ovaries.

Dr. HERMAN J. BOLDT of New York City said that regarding the case reported by Dr. Morris, he (Dr. Morris) had been waiting for two weeks for him to supply a patient who had had normal ovarian tissue. He did a ventrosuspension on a woman and gave him half of one ovary. In the case of his patient Dr. Morris had removed both ovaries two years previously. The patient had not menstruated during that interval. After the transplantation of ovarian tissue, the patient began to menstruate again, subsequently became pregnant, and bore a child. The child was still living.

Ureteral Stricture; Report of 100 Cases.—Dr. GUY L. HUNNER of Baltimore said that ureteral stricture was far more frequent than was formerly suspected. Too much importance was given in the literature to congenital stricture. Most of the cases were due to systemic infection from a distant focus, such as the tonsils, teeth, or sinuses. The symptoms were local pain at the site of the inflammatory area, renal pain due to back pressure, referred pain to the bladder, rectum, hip, thigh, etc. . . . There was elevation of temperature with and without infection of the urine. Gastrointestinal symptoms and mental symptoms were referred to. The diagnosis must be made from kidney lesions and from lesions of practically every abdominal organ, and also from sacroiliac and other hip joint lesions. The treatment consisted of dilatation from bladder approach or of retrograde dilatation through the extraperitoneal route.

A Cystoscopic Study of the End Results of Various Forms of Cystocele Operations. — Drs. LEROY BROUN and REGINAL M. RAWLS of New York City stated that for the purpose of this preliminary report twelve patients were found to have a practically normal plane of the base of the bladder. Three of these had a mild trigonitis. The character of cystocele operations done upon these patients varied greatly. The larger number consisted of freeing the bladder from the vaginal mucosa and uterus, coapting the prevesical fascia under the bladder and approximating the vaginal mucosa after the excess had been removed. A few of the operations consisted of a simple separation of the vaginal mucosa on each side of the median incision, the removal of the excess, and an approximation of the edges under the bladder. One was after the old Emmet method, and one by anchoring the bladder on a higher plane to the broad ligaments and uterus, after its previous separation from the vaginal mucosa and uterus. In another series of cases the base of the bladder was found to be thrown into horizontal folds of varying degrees of prominence. There were eight patients in this group. In half of these there was no displacement of the mouths of the ureters; in the other four this displacement was very noticeable. The character of operations done in these cases was as follows: In three, after the separation of the bladder from the vaginal mucosa and the uterus, the prevesical fascia was united under the bladder, the excess of the mucosa was removed, and the edges coapted. In three others, after the separation of the bladder from the mucosa and the uterus, the base of the bladder was anchored by silk sutures higher up on the broad ligaments and uterus, or to the shelf made by the united broad ligaments, if the uterus was removed. In one case an oval denudation was made on the anterior wall and the edges coapted. The cystoscopic examination of these eight patients showed the base of the bladder in each instance to be thrown into horizontal folds of varying depth and extent. In some the mouths of the ureters were found displaced; in others, in addition to the displacement, one or both could not be located. Trigonitis of a mild degree of the granular or membranous type was the usual accompaniment. The uniform method of putting 300 c.c. of water in the bladder was followed in the entire cystoscopic study. When abnormalities were found, as in these and other cases, the bladder was distended to its full capacity to determine whether or not the folds would disappear. In no instance was this accomplished. The convolutions and sulci remained as first seen under the 300 c.c. distention, showing that they were of a permanent character. The kind of operation done did not seem to bear in a marked degree upon the character and extent of the permanent folds found to be present. This review of the study of the end results on these patients, from the viewpoint of the anatomical condition in which the base of the bladder was left, was not of a flattering character. That the abnormal conditions found were of a permanent character could not be questioned, since they did not disappear under full distention.

A Vaginal Subtotal Hysterectomy Technique, Equally Applicable to Cases with or without Procidentia Uteri or Cystocele.—Dr. DOUGAL BISSELL of New York City described a technique for subtotal vaginal hysterectomy. Subtotal vaginal hysterectomy was preferable to total hysterectomy when the vaginal route for hysterectomy was the route of choice. Subtotal vaginal hysterectomy was less difficult to perform than total vaginal hysterectomy. There was less liability to secondary hemorrhage, and should secondary hemorrhage occur it was under easy control. As the uterine arteries were not tied the uterine and ovarian circulation were not interfered with. There was minimum liability to sepsis, as the posterior cul-de-sac was not opened. Peritoneal drainage was not resorted to. The union was primary. When subtotal vaginal hysterectomy was performed, procidentia of the uterus and cystocele could be corrected at the same time. For procidentia the uterosacral ligaments were in addition shortened. For cystocele the newly formed uterine body was interposed, as in the Watkins operation, or the body could be returned to the peritoneal cavity and the posterior surface and part of the base of the bladder sutured to its anterior face. Reconstruction of the fascial shelf between the bladder and the anterior vaginal wall then became necessary.

Clinical Study of Blood Pressure, Pulse Pressure, Homoglobin in Postoperative Shock, Postoperative Hemorrhage, and Postoperative Cardiac Dilatation. — Dr. JOHN O. POLAK of Brooklyn, N. Y., stated that the deductions which one might draw from his studies were. (1) There is a constant rise of from five to fifteen points in the hemoglobin readings following anesthesia with ether, when such anesthesia occupies more than 30 minutes. Consequently, allowance must be made for this rise in using hemoglobin estimations as a diagnostic sign in internal bleeding. (2) The erythrocyte count is also increased, but its variation from the preoperative is so slight that it does not warrant any conclusions. (3) In the majority of cases there is a moderate fall in both the systolic and diastolic blood pressure following ether anethesia. The blood pressure returns to normal, that is, to preoperative reading, in from twelve to forty-eight hours. The inhalation of oxygen after the withdrawal of the ether vapor diminishes this fall in blood pressure, but is only transient in its effect. (4) In cases of shock, especially where there has been much blood lost during the operation, the fall in blood pressure is greater than after long operation without blood loss, dropping from ten to fifteen minutes. (5) The pulse pressure is a better index of hemorrhage or cardiac failure than the systolic pressure. (6) There is a constant rise in the leucocyte count in hemorrhages, while the leucocytes fall in shock.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL COUNCIL OF CANADA.

Montreal, October 10, 11 *and* 12, 1916.

(*Concluded from page* 222.)

SURGERY.

1. Fracture of patella: Causes, symptoms, and modes of treatment.
2. Dislocation of the Hip Joint: Varieties, symptoms (clinical features), and modes of reduction.
3. Carbuncle: Definition, pathology, symptoms, diagnosis, complications, and treatment.
4. The pathology and symptoms of tuberculosis of the kidney: Outline your method of examination, with findings, leading to a diagnosis.
5. Cholelithiasis: Diagnosis, complications, and treatment in detail.
6. Give the history, clinical features, and treatment in detail of a typical case of middle meningeal hemorrhage.

MEDICINE.

1. Discuss the important points in the differential diagnosis of cardiac dilatation and pericardial effusion.

2. How would you establish a differential diagnosis between (*a*) acute lobar pneumonia, (*b*) congestion (active) of the lungs, (*c*) acute pneumonic phthisis?

3. Write what you know about (*a*) the etiology and (*b*) the diagnosis of epidemic cerebrospinal meningitis.

4. How would you treat a case of typhoid fever complicated by intestinal hemorrhage, giving (*a*) the hygienic, (*b*) the dietetic, and (*c*) the medicinal treatment?

5. Describe the method of giving salvarsan. Discuss the dosage of the remedy, pointing out the indications for its use.

6. A woman aged fifty-one years was seen in a restless state, with twitching of muscles. She was slow in answering questions or obeying orders. Her speech was rather thick. There was no fever. The pulse was regular and of high tension (200+). There was no cough, cyanosis, nor edema. The pupils were equal with normal reflexes, while the tendon reflexes were greatly exaggerated. There was no paralysis. The history showed that the patient had suffered recently severe headaches with frequent vomiting. Recently also her strength had failed and she occasionally complained of severe præcordial pain, yet no pericardial signs were made out. The urine had been free from albumin but now contained blood. The Wassermann was negative. Kernig and Babinsky signs were absent. Discuss the diagnosis and point out further clinical methods useful in establishing a diagnosis.

ANSWERS.

SURGERY.

1. FRACTURE OF THE PATELLA is *caused* by muscular violence and by direct violence. "*Fracture by direct violence* is often star-shaped, and the aponeurosis is not torn, so that the fragments are not separated. Signs of local injury, pain, and bruising are apparent. *Treatment* consists in keeping the limb at rest on a back-splint and applying an ice-bag. Early passive movement and massage are advisable.

"*Fractures due to muscular violence* are more common. They are always transverse; the aponeurosis and capsule on either side of the patella are torn, and the fragments are separated. The patella is broken when poised on the condyles in the semiflexed position. It is then held down by the ligamentum patellæ, and when the quadriceps is suddenly contracted, as in a person trying to regain the upright position, the patella snaps. *Signs:* There is loss of the power of extension, separation of the fragments, and pain, followed by distension of the joint with blood, and synovitis. The aponeurosis is torn at a different level to the fracture, and hangs over between the fragments. The lower fragment is tilted forwards. *Treatment:* The best method is open operation, and wiring four or five days after the accident; for only by this means can bony union be obtained. The obstacles to bony union, without open operation, are that the tilting of the lower fragment cannot be overcome in any other way; the aponeurosis cannot be removed from between the fragments, nor the blood-clot from the joint, except by slow absorption. If no operation is done the union is fibrous, and the fibrous bond will stretch unless the patient be condemned to a stiff knee for six to twelve months. A working man is badly off with either a stiff knee for that time or a stretched bond forever. The *open operation* must necessarily be aseptic. The knee may be washed out with 1 in 40 carbolic or 1 in 2,000 bichloride without injury, or sterilized saline solution may be used. The joint is opened by a horseshoe incision, the blood-clot is removed, the aponeurosis clipped away, the bones drilled and fixed in accurate apposition with silver wire, and the wound is closed without drainage. As atrophy of the quadriceps occurs early, massage and passive movements must be begun in ten days. The patient may go about on crutches in three weeks. Bony union is firm in six weeks. *Retentive apparatus* is used where operation is inadvisable or refused. This may be plaster of Paris, but does not admit of massage. Another plan is to use mole-skin plaster covering the thigh, and kept fastened to the lower part of a back-splint by elastic extension. Or poroplastic may be moulded, one piece over the thigh, the other over the leg, the upper piece being cut out to fit around the upper part of the patella, and the lower to fit around the lower part. These are bandaged firmly to the limb, and fastened together on either side of the patella by Malgaigne's hooks, which are screwed up daily as they become loose. At the end of six weeks the patient is allowed up, but must wear a knee-splint to keep the joint stiff for six to twelve months."—(*Aids to Surgery.*)

2. HIP JOINT DISLOCATIONS.—*Varieties—Backward:* (1) On to the dorsum ilii; (2) on to the sciatic notch. *Forward:* (3) On to the obturator foramen; (4) On to the pubis.

Dorsal dislocation: Head of femur lies on the dorsum ilii, and can be felt in the buttock. The obturator internus is ruptured in most cases. The short rotator muscles are lacerated. The trochanter lies well above Nelaton's line and approximated to the anterior superior iliac spine. The leg is shortened two to three inches. The iliotibial band is relaxed. The leg is flexed, adducted, and inverted. The femur crosses the lower third of the opposite thigh. The toe rests on the opposite instep. A hollow exists in Scarpa's triangle.

Sciatic dislocation: Similar to the above, except in the following:—The obturator internus tendon is intact and lies over the neck of the femur, holding it down in the sciatic notch. Shortening amounts only to one inch or less. The axis of the femur crosses the opposite knee. The great toe rests on the dorsum of the opposite great toe.

Treatment of the backward dislocations: Flex the knee and thigh in position of adduction. Abduct the thigh and evert simultaneously. Bring the leg down straight. "Lift up, bend out, roll out."

Obturator dislocation: The head of the bone lies on the obturator externus in the obturator foramen. The abductor muscles are lacerated. The trochanter is obscured, the iliotibial band is tense. The leg is lengthened, the toes point forward and outward. Flexion, abduction, and rotation outward are well marked. The head of the femur is felt in the perineum. The capsule is torn in its lower part. Pain referred to the distribution of the obturator nerve.

Public dislocation: Similar to the above except: The femoral head is felt under Poupart's ligament. The leg is shortened about one inch. Abduction and eversion are more marked, the toes pointing outward.

Treatment of forward dislocations: Thigh is flexed in a position of abduction. Adduct the thigh and then invert it. Bring the thigh down straight. "Lift up, bend in, roll in."—(From Groves' *Synopsis of Surgery.*)

3. *Carbuncle* is a localized inflammation of the subcutaneous tissue, which has gone on to sloughing. Staphylococci are the exciting cause; diabetes, albuminuria, infective fevers, and lowered vitality are the predisposing causes.

The disease begins as an infiltration of a patch of subcutaneous tissue, which is hard, painful and tender, and the skin over it red and hot. The infiltration may extend till it is the size of a dinner-plate, and the inflammation ends in sloughing and suppuration, not only of the subcutaneous tissues, but of small areas of the skin over it, so that openings develop in the skin, and allow of the exit of pus and sloughs. The openings extend, the sloughs separate, and the wound heals by granulation. The back is a common situation. Sometimes the face is affected, and there is then a danger of thrombosis extending to the cavernous sinus and producing pyemia.

Treatment: Anesthetize, scrape away the slough, treat the surface with pure phenol, dress with antiseptic gauze, and give the patient good food and tonics.

4. "*Tuberculous disease of the kidney* occurs in three forms: 1. As part of general tuberculosis, and giving rise to no special symptoms. 2. It may extend upwards from tuberculous disease of the bladder and affect both kidneys. The mucous membrane of the ureters, pelvis, and calyces, and finally the kidney itself, become converted into tuberculous granulation tissue. The kidneys become enlarged owing to hydronephrosis or pyonephrosis, and a perinephric abscess may follow. Death occurs from chronic toxemia or uremia. Treatment is of little use. 3. Primary tuberculosis of the

kidney is unilateral. A focus of tubercle begins in the cortex, caseates, and spreads to the pelvis, infecting it. Pyonephrosis follows, and infection of the bladder may succeed it. Perinephric suppuration may also occur. The *symptoms* at first consist of aching pain in the loin and frequent micturition, not improved by rest. Hematuria comes on early and without apparent cause, is not increased by movement or improved by rest. Pus is usually present in acid urine, and the *Bacillus tuberculosis* may in some cases be detected. In the late stages the kidneys may be felt much enlarged. The *diagnosis* is doubtful in the early stages, unless bacilli can be demonstrated by the microscope or inoculation of a guinea-pig. The hematuria is much slighter than in cases of renal calculus, and is not influenced by rest. The hemorrhage is not so profuse as in cases of new growth. Slight attacks of renal colic may occur from the passage of caseous matter, but not severe attacks like those due to calculus. An exploratory incision settles the diagnosis in doubtful cases."—(*Aids to Surgery.*)

5. *Gallstones.* "While the calculus remains free in the gall-bladder, usually there are no symptoms. Impaction of the stone in the common duct gives rise to intermittent jaundice, following sharp pain in the right hypochondriac or epigastric region, frequently radiating toward the right scapula, nausea, vomiting, sweating, depression, and often intermittent fever (Charcot's intermittent fever). When the stone is impacted in the cystic duct, jaundice is less common, but the hepatic colic is severe, and dropsy of the gall-bladder may occur. The diagnostic points are the age, sex, history of previous attack, with jaundice and intermittent fever, location of the pain, dark, amber-colored urine, containing bile, and sometimes the finding of the stone in the feces.

Complications and sequels. (1) Suppurative cholecystitis (empyema of the gall-bladder); (2) secondary abscesses; (3) permanent jaundice, with production of Charcot's intermittent fever; (4) ulceration and passage of stone into the intestine; (5) obstruction of the bowels from gallstone; (6) stricture of the ducts and atrophy of the gall-bladder."—(*Pocket Cyclopedia.*)

Surgical treatment. Cholecystotomy is done through an incision parallel to and 1½ inches below the costal margin over the gall-bladder. The liver is drawn up and the intestines packed away with gauze. If the gall-bladder is distended the fluid is removed by tapping it with a trocar and cannula. The opening is then enlarged, and the stones are removed with a scoop. The bile-ducts are examined along their whole course by a finger externally, and by a long probe internally. If the interior is fairly healthy, the opening is sutured with two layers of continuous sutures and the abdomen is closed. Usually it is necessary to drain the gall-bladder for a time, in which case the margins of the opening are stitched to the peritoneum and transversalis fascia of the abdominal wound. The fistula thus established soon closes if there is no obstruction to the passage of the bile into the intestine. If not, it must be closed by a plastic operation or cholecystenterostomy."—(*Aids to Surgery.*)

6. Middle meningeal hemorrhage. "*Symptoms:* When not obscured by some other cerebral lesion, the typical symptoms are—(1) temporary concussion; (2) a lucid interval of a few minutes to a few hours; (3) gradually increasing drowsiness ending in coma. If the hemorrhage is rapid or there is cerebral laceration as well, there may be no interval of consciousness. In addition there may be, from pressure on the motor area, twitching of the corresponding parts followed by paralysis. The pupil on the injured side becomes first fixed and dilated, the other following. When the coma is well marked the pulse is slow and full, and the breathing is stertorous. When the brain is lacerated there are alternating tonic contraction and relaxation of the muscles supplied from the injured area. The *Prognosis* is very grave. The *Diagnosis* is difficult, unless the symptoms are typical, and they seldom are. *Treatment* consists in trephining, removing the blood-clot, and stopping the bleeding. A flap is turned down, and a trephine hole made over a spot 1½ inches above and behind the external angular process exposes the anterior branch. After the blood-clot is removed the bleeding-point is searched for and tied; if it is not seen, more bone must be clipped away. If the bleeding comes from a canal in the bone, it may be stopped with gauze, sponge, or aseptic wax. If the brain then expands, the bone may be replaced and the wound stitched un without drainage; if not, the bone must not be replaced, and the wound should be drained for twenty-four hours. The posterior branch can be reached by a hole made just below the parietal eminence."—(*Aids to Surgery.*)

MEDICINE.

Pericarditis with Effusion	Cardiac Dilatation
Recent history of gout, acute rheumatism, acute infectious or septic disease, scurvy, nephritis, or tuberculosis, chronic gonorrhea.	Usual history of chronic valvular disease of the heart.
Fever and slight pain often associated.	No fever or pain, as a rule.
Nervous symptoms are often present.	Absent or but slight.
Inspection often reveals bulging. Apex-beat is elevated, feeble, and later absent.	Apex-beat usually visible, wavy, and diffuse.
Heart's impulse usually absent, or occupies center or upper border of dull area. Friction fremitus may be present.	Though feeble, the impulse is palpable.
Percussion shows a triangular flat area, and the boundary line alone changes on altering the position of the patient. There is dull tympany in the axillary region. Dullness over left lung below angle of scapula common.	Dull area varies with the chambers dilated; it is co-existent with a wavy impulse, does not extend so high (except in mitral stenosis), and does not vary with change of position. There is no dull tympany.
Auscultation shows the first sound distant and muffled; a friction rub is often present.	First sound clear, short, and sharp resembling the second sound. Friction murmur rare, but an endocardial murmur may appear later.

—(From Anders and Boston's *Diagnosis.*)

2. Lobar Pneumonia. *Diagnosis:* (1) From *acute phthisis:* The symptoms and physical signs of *lobar pneumonia* and *acute pneumonic phthisis* may be the same for the first eight or ten days; at this period the fever in *pneumonia* drops by crisis; whereas in *phthisis* the fever continues for some time longer and the patient gets worse; the sputum contains tubercle bacilli and elastic fibers, and instead of retaining the rusty color it becomes purulent and greenish.

In *pneumonia*, the breathing is very rapid, the pulse-respiration rate is disturbed, the fever is usually high, and runs a regular course, crepitant râles are heard at first, then signs of consolidation follow, and crepitant râles again succeed.

In *phthisis*, the breathing is hurried and there is dyspnea; the fever is often high, but does not run a regular course. At first the signs are those of bronchitis, followed by consolidation, a softening, or excavation in different parts of the lungs; sometimes there is nothing to be heard but scattered râles.

Acute pulmonary congestion is "undistinguishable from the first stage of pneumonia."—(Butler.)

3. Epidemic cerebrospinal meningitis. *Etiology:* The *Diplococcus intracellularis meningitis.* Sporadic cases may be due to the pneumococcus, streptococcus, colon bacillus, typhoid bacillus, bacillus of influenza, or gonococcus; but the epidemic form is always caused by the *Diplococcus intracellularis.* It enters the system through the mucous membrane of nose, mouth, or pharynx, and reaches the meninges by way of the lymphatics or the circulation. The disease may be conveyed by "carriers." *Diagnosis* is made from (1) the symptoms, (2) Kernig's sign, and (lumbar puncture. *Symptoms:* The onset is generally sudden, with headache, rigors, stiff neck, opisthotonos, vomiting,

moderately high (102° F.) and irregular fever, full and rapid pulse, herpes, photophobia; convulsions, delirium, monoplegia or hemiplegia, enlarged spleen, retracted abdomen, and disturbed reflexes may be present *Kernig's sign* is obtained (if the thigh is flexed at right angles to the abdomen, the leg cannot be fully extended on the thigh, as it can in health, owing to the contraction of the flexor muscles). By *lumbar puncture*, some of the cerebrospinal fluid may be withdrawn and examined for the presence of the diplococcus.

4. *General treatment of typhoid fever.* "As soon as the nature of the disease is recognized the patient should be confined to bed. The room should be large and airy, and provided with efficient means of securing thorough ventilation. The temperature of the room should be maintained between 65° and 70° F. The bedpan must be used from the beginning until convalescence is well advanced. The stools and urine should be rendered innocuous before being thrown out. This may be done by treating the evacuation with twice its volume of a 1 per cent. solution of chlorinated lime or a 5 per cent. solution of carbolic acid, and allowing it to stand in a covered vessel for two hours before emptying it into the closet. Soiled clothing should be thoroughly boiled. The *diet* should be liquid or semisolid, unirritating, and easily digestible. Milk alone (6 ounces every four hours) does not supply the required number of calories (2,500-3,000), but, as a rule, it should form a large part of the diet. It may be given diluted with lime water, or as buttermilk, malted milk, koumiss, junket, or ice cream. Among other suitable foods may be mentioned raw or soft boiled eggs, chicken jelly, milk toast, strained oatmeal gruel, potato puree, tea, coffee, cocoa, fruit juices, wine jelly, and custard. Beef tea and broths may be harmful. In the event of digestive disturbances the diet should be restricted for a time to whey or albumin water. Water, plain or flavored (lemonade, soda water, etc.), should be given in large amounts between the feedings. When the first sound of the heart becomes weak and the pulse dicrotic, alcohol is usually indicated. From 4 to 8 ounces of whisky or brandy may be given in the twenty-four hours, the amount being determined by the general effect. The *cold bath* or the *cold pack* affords the best means of controlling fever and preventing the development of severe nervous symptoms. It may be employed every three or four hours when the temperature is 102.5° F. or over. Hemorrhage, signs of perforation, menstruation, and great prostration are contraindications.

"*For the hemorrhage:* Absolute rest is imperative. Cold bathing should be suspended. It is advisable to elevate the foot of the bed. An ice-bag may be applied with advantage to the right iliac region, and ice may be given to suck. The best drug is morphine (⅙ to ¼ grain) hypodermically. Ergot is useless. In cases of recurrent hemorrhage calcium lactate (10 grains thrice daily) and gelatin may be given by the mouth."—(Stevens' *Manual of Practice.*)

5. *Salvarsan is indicated* in: "(*a*) Early cases of syphilis in which contagious manifestations are appearing in rapid succession, in spite of efficient mercurial medication. (*b*) Cases in which, for family or social reasons, it is of special importance to limit the production of infective material or cause the disappearance of symptoms in the shortest possible time. (*c*) Cases in which the symptoms are recalcitrant to the action of mercury, or in which, from idiosyncrasy, that drug cannot be exhibited in sufficient dose. (*d*) Cases of syphilophobia and syphilomania, whether showing symptoms or not; its psychic action in these instances being of greater importance than its therapeutic effect. (*e*) Very early cases of the sequelæ of the luetic infection, before organic changes have occurred."

Salvarsan is contraindicated in: "(a) Cases that are doing well, *i.e.* in which the disease is pursuing its normal mild course under ordinary medication. (*b*) Cases with serious organic lesions of the eyes, kidneys, heart, or other internal organs. (*c*) Cases with post-syphilitic or parasyphilitic disease of the internal organs, more especially of the nervous system."—(*Progressive Medicine.*)

It may be administered intramuscularly or intravenously. The intravenous injection is described by Hirsch as follows: Two graduated glass containers of 250 c.c. capacity are used. Into one is poured 150 to 200 c.c. of sterile salvarsan solution. The other is filled with a like volume of sterile saline solution (made with sterile distilled water and chemically pure sodium chloride). The saline solution is allowed to flow out of the needle so as to expel all air from the tube. The stopcock is now reversed, allowing the salvarsan solution to flow out of the needle, thereby expelling all air from its tubing. The stopcock is now reversed to its former position, until the saline solution is running in a slow, even stream from the needle. The desired site of puncture is selected on the arm or at the elbow, and the needle is gently pushed or thrust through the skin into the vein. Meanwhile the saline solution is continuously running from it. The needle is held at about an angle of 10 to 15 degrees to the skin surface, depending on the prominence and caliber of the vein. Care must be exercised not to push the needle through both walls of the vein. This accident can best be avoided by not introducing too long a surface of the needle into the tissues.

Dosage depends on the type and stage of the disease. Generally from 0.1 to 0.6 gm. is used at intervals of from 5 to 10 days.

6. The diagnostic possibilities are: Uremia, with impending convulsions and coma, with chronic nephritis; cerebral thrombosis (in spite of the high blood pressure); small hemorrhage or tumor in the neighborhood of the island of Reil; arteriosclerosis, with vascular spasm; diabetes. Further clinical methods would include examination of the fundus oculi; complete examination of urine, including a measure of the total quantity passed by day and by night separately, an estimation of the total urea eliminated, the phenolsulphonephthalein test, and tests for sugar.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	
Arizona*	J. W. Thomas, Phoenix	Phoenix	Oct. 2
Arkansas	T. J. Stout, Brinkley	Little Rock	Nov. 13
California	C. B. Pinkham, Sacramento	Los Angeles	Oct. 9
Colorado	David A. Strickler, Empire Building, Denver	Denver	Oct. 2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	
Delaware	J. H. Wilson, Dover	Dover	Dec.
Dist. of Col'bia	E. P. Copeland, Washington	Washington	Oct. 9
Florida*	E. W. Warren, Palatka	Palatka	
Georgia	C. T. Nolan, Marietta	Atlanta	Oct. 9
Idaho*	Charles A. Dettman, Burke	Pocatello	Oct. 2
Illinois		Chicago	
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 8
Iowa	G. H. Sumner, Des Moines	Iowa City	
Kansas	H. A. Dykes, Lebanon	Topeka	Oct. 9
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. L. Leckert, New Orleans	New Orleans	Dec. 6
Maine	F. W. Searle, Portland	Portland	Nov. 13
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 11
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston	Sept. 11
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 9
Minnesota	T. McDavitt, St. Paul	Minneapolis	Oct. 2
Mississippi	J. D. Gilleylen, Jackson	Jackson	
Missouri	G. H. Jones, Jefferson City	Kansas City	Sept. 24

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PROCEEDINGS OF THE MEDICAL ASSOCIATION OF THE ISTHMIAN CANAL ZONE for the Half Year, January, 1916, to June, 1916. Vol. IX, Part 1. Illustrated. 190 Pages. Published by The Health Department, The Panama Canal.

TWENTY-SECOND REPORT OF THE BOARD OF HEALTH of the Town of Montclair, New Jersey. From January 1, 1917, to December 31, 1916. 64 Pages. Published by Wynkoop-Hallenbeck-Crawford Co., Lansing, Michigan (State Printers). 1917.

HEALTH SURVEY OF NEW HAVEN. A report presented to the Civic Federation of New Haven by CHARLES-EDWARD AMORY WINSLOW, JAMES COWAN GREENWAY, and DAVID GREENBERG of Yale University. 114 Pages. Illustrated. Price, 75 cents. Published by Yale University Press, New Haven, Conn.

NOTES ON MILITARY ORTHOPAEDICS. By COLONEL ROBERT JONES, C.B., with an introductory note by SURGEON-GENERAL SIR ALFRED KEOGH, G.C.B. Illustrated. 132 Pages. Published for the British Red Cross Society by Cassell & Company, Ltd., London, New York, Toronto and Melbourne. 1917.

ASTHMA. Presenting an exposition of the Non-passive expiration theory. By ORVILLE HARRY BROWN, A.B., M.D., Ph.D., with a foreword by GEORGE DOCK, Sc.D., M.D. 36 Engravings. 330 Pages. Published by C. V. Mosby Co., St. Louis, Mo. 1917.

DREAM PSYCHOLOGY. By MAURICE NICOLL. 194 pages. Price, $2. Published by Oxford University Press, New York City.

BUILDING HUMAN INTELLIGENCE. By DR. ARNOLD LORAND. 451 pages. Price, $3. Published by F. A. Davis Co., Philadelphia, Pa.

POLIOMYELITIS IN ALL ITS ASPECTS. By JOHN RUHRAH, M.D., and ERWIN E. MAYER, M.D. Illustrated with 118 engravings and 2 plates. 297 pages. Price, $3.23. Published by Lea & Febiger, Philadelphia, Pa.

MUSKETS AND MEDICINE or ARMY LIFE IN THE SIXTIES. By CHARLES BENEULYN JOHNSON, M.D. 276 pages. Illustrated. Price, $1.50. Published by F. A. Davis Co., Philadelphia, Pa.

PRACTICAL MATERIA MEDICA AND PRESCRIPTION WRITING. With illustrations. By OSCAR W. BETHEA, M.D., Ph.G., F.A.C.S. Second revised edition. 562 pages. Price, $4.50. Published by F. A. Davis Co., Philadelphia, Pa.

HANDBOOK OF ANATOMY. Being a Complete Compend of Anatomy. By JAMES K. YOUNG, M.D., F.A.C.S. Fifth edition, revised and enlarged. With 154 engravings, some in colors. 435 pages. Published by F. A. Davis Co., Philadelphia, Pa. Price, $2.

THE MEDICAL CLINICS OF NORTH AMERICA. July, 1917. 193 pages. Illustrated. Published bi-monthly by W. B. Saunders Co., Philadelphia and London. (Six numbers a year.) Price per year, $10.

DENTAL MATERIA MEDICA AND THERAPEUTICS. With Special Reference to the Rational Application of Remedial Measures to Dental Diseases. A Text-Book for Students and Practitioners. By HERMANN PRINZ, A.M., D.D.S., M.D. Fifth edition, enlarged and revised according to the U. S. Pharmacopeia. Ninth decennial revision. 659 pages. Illustrated. Price, $5. Published by C. V. Mosby Co. St. Louis, Mo. 1917.

MANUAL OF THE DISEASES OF THE EYE. For students and general practitioners. By CHARLES H. MAY, M.D. Ninth edition revised. With 377 original illustrations, including 22 plates, with 71 colored figures. 440 pages. Price, $2.50 net. Published by William Wood & Company, New York.

STUDIES FROM THE DEPARTMENT OF PATHOLOGY OF THE COLLEGE OF PHYSICIANS AND SURGEONS. Columbia University, N. Y. Vol. XV, 1916 Reprints.

THE MASTERY OF NERVOUSNESS BASED UPON SELF REEDUCATION. By ROBERT S. CARROLL, M.D. 346 pages. Published by The Macmillan Co., New York. Price, $2.

Therapeutic Hints.

Therapeutic Action of Sponge Baths.—Mary Larter states that sponge baths are beneficial for the metabolism and building up of the body tissues; the properly given cold-water sponge bath aids in the oxidation of the carbohydrates, while the warm sponge bath promotes the oxidation of the nitrogenous elements, the degree of oxidation depending largely upon the duration and temperature of the application. She warns that cold water is rarely borne well without at the same time applying friction. Therefore, the physiological effects of a properly given sponge bath of the correct temperature and desired friction may be summed up as follows: (1) Increased vitality; (2) increased activity of the nerve centers; (3) increased muscular tone; (4) increased activity of the kidneys, skin and liver; (5) more oxygen inhaled, due to increased respiration; (6) increased blood pressure; (7) stronger, slower pulse; (8) tonic effect upon the heart; (9) increase of the blood corpuscles, especially the white ones, thus demonstrating the legitimate use of baths for aiding phagocytes. In administering antifebrile sponge baths it requires a person with a calm, quiet temperament to do the work properly. The strokes with the wet sponge must be long and soothing, and executed with considerable pressure. If friction be desired (depending upon physician's orders) use water of correct temperature tested accurately with a thermometer, to be given for specified length of time. Articles needed for sponge baths are one rubber sheet, one bath towel, two cotton towels, one small towel for the abdomen, one hot water bag and cover, one ice cap, one foot tub, half full with water of 80° to 90° F. and one bath thermometer. Have everything in readiness, first apply ice cap to patient's head, hot water bottle to feet, then remove top covers of bed and substitute a cotton sheet; then pass the rubber sheet, covered with a cotton sheet, under the patient and lastly cover the public region with a small towel. Begin the sponging with the same stroke as in ordinary cleansing, having plenty of water in the washcloth. Rinse washcloth frequently and gradually cool water by addition of ice, thus obviating the risk of wetting the mattress because of possibly a defective rubber sheet. This should be continued for twenty to thirty minutes, and, if carefully done, the reduction in the temperature may be noted in half an hour following the termination of the sponge bath. Sponge baths of low temperature and of a certain duration will cause a rise of blood pressure, whereas hot sponging primarily causes heightened blood pressure, followed by relaxation of the blood vessels and consequent fall of blood pressure, anemia of the brain through the continued use of hot applications can produce faintness; warm sponging slightly increases the number of red cells and decreases the leococytes in the parts not exposed to the water, and thus warm sponge baths could be used in the treatment of anemia. The primary effect of both hot and cold water on the body is stimulating, while its secondary effect in the prolonged hot sponge bath is sedative, then weakening; in the cold sponge bath, the secondary effect is stimulating; when prolonged, depression follows overstimulation.—*Clinical Medicine.*

TREATMENT OF CHRONIC BRIGHT'S DISEASE.*

BY J. M ANDERS, M.D., LL.D.,

PHILADELPHIA, PA.

THERE are two principal criteria which should serve to guide us in the treatment of chronic Bright's disease. They are, the general condition of the patient as it is influenced by the progress of the affection, and the rate of metabolic excretion as determined by modern methods of examination. We should also pay due regard to the results of clinical and microscopical studies of the urine, although in my experience both albumin and tube casts have, at times, shown a tendency to increase under a judiciously restricted diet on the one hand and to remain uninfluenced by a pretty generous diet on the other.

Without stopping to attempt to remove the touch of vigorous professional confidence in the percentage of albumin and the number and variety of tube casts as an index to the severity of the morbid process, and making it the foundation for prognosis and treatment, I feel that we have depended too exclusively on this somewhat uncertain standard in the past.

I propose considering the two criteria mentioned above for a moment separately so far as practicable, believing that most light may be thus thrown on the present-day means of dealing with this important disease.

The Rate of Metabolic Excretion.—This must be gauged by the most modern and approved methods. The amount of urea excreted in the twenty-four hours is an indication of the outcome of the case, and should be carefully and repeatedly estimated.

Among the substances excreted with great difficulty by a diseased kidney is creatinin. In this connection it is of interest to note that Myers and Lough have shown that an estimation of the blood creatinin is of prognostic value, *e.g.* over 5 mg. per 100 c.c. of blood having invariably terminated fatally in from a few days to two months, while figures from 3 to 15 mg. are to be regarded as decidedly unfavorable. It is essential, therefore, that substances which like urea, creatinin, pigments, hippuric acid, and phosphates are excreted with difficulty, should be allowed in minimal amounts in Bright's disease. To avoid the ill effects of phosphoric acid, von Noorden[1] recommends that calcium carbonate be added to substances containing it.

*Read at the eighteenth annual meeting of the American Therapeutic Society, New York City, June 1 and 2, 1917.

The test meal for renal function probably gives the earliest evidence of diminished kidney efficiency. Mosenthal and Lewis[2] hold phenolsulphonephthalein excretion and Ambard's coefficient are tests which enable one to follow most minutely the progress of renal disease.

General Condition of the Patient during the Progress of the Disease.—While seeking to afford protection to the diseased kidney by extreme moderation in diet, especially in proteins, due attention is to be paid to the matter of avoiding deleterious effects to all other organs—to the metabolism. The strength of the patient is to be preserved by adapting sound hygienic, therapeutic, and dietetic principles to the individual case.

Extremes of mental and bodily activity are to be avoided and the habits and mode of life of the patient regulated, the aim being to maintain the nutritive equilibrium, without producing irritation of the renal epithelium. All noxious substances entering into the etiology must be avoided and removed as far as possible. Primary foci of infection, *e.g.* in the teeth and tonsils, or elsewhere, should receive particular attention. By diminishing or removing such irritants as uric acid, alcohol, lead, and the like, the cardiovascular system is also conserved—a point of vital importance. The cooperation of the patient is always necessary to the end that the directions given shall be carried out persistently and faithfully.

The value of a change of residence to a warm, dry, and mild climate in many cases of the chronic interstitial form of Bright's disease is undoubted. The variability and humidity of temperate climates, particularly during winter, are aggravating factors in this disease, while a sea voyage or a sojourn at some resort where the soil is dry and sandy, and the climate warm and equable, may be highly beneficial.

Diet.—The chief control of chronic Bright's resulting from treatment is found in diet coupled with the foregoing suggestions pertaining to mode of life, rather than in drugs. The dietary restriction should be both quantitative and qualitative. I quite agree with Shattuck[1] that a varied diet is more likely than a monotonous one to promote the making of good blood and improving the general nutrition, and that of the myocardium in particular.

An excess of protein, which is always harmful, can be avoided only by a close study of the functional capacity of the kidney at short intervals of time, and the repeated estimation of the urea and creatinin content of the circulating blood. By pursuing such a course it is found that ofttimes greater latitude may be extended without injury to

the sick kidney, and thus aid decidedly the general metabolism. In this connection, the view of Foster and Davis,[4] to the effect that in cases in which there is no great amount of edema, we must allow considerable water, the while we diminish the protein intake, in order to eliminate the solids and retained nitrogen, is sound and to be adopted.

On the other hand, when dropsy of a more marked degree is present, the fluid intake should be restricted to a total daily amount not exceeding one liter. In this class of cases, composed largely of instances of chronic parenchymatous nephritis, a salt-free, or, what is more practicable, a salt-poor dietary, is a most useful adjuvant to efforts at removing the edema.

Whilst whole milk should make up a considerable portion of the diet, von Noorden has pointed out that milk contains on the whole too much protein, and recommends that it should be restricted to three pints a day, to which a pint of cream should be added. The writer has found skim milk and buttermilk, in appropriate quantities, of signal value in cases in which dropsy is marked.

Recently, Terwaert and Van Lier[5] have put forth the claim, based on their experiments and clinical experience, that restriction to a milk diet in cases of nephritis with retention of urea is decidedly harmful.

In general, a mixed diet will be of advantage; proteins in quite limited amounts,* greens, fruits (especially fruit juices), pure fats, and light, well cooked farinaceous dishes and cereals (except oatmeal) may be allowed. Cocoa may be allowed as a beverage at the morning meal. The effect of a given restricted dietary is to be noted by making careful observation of the bodily weight and of repeated tests of the functional capacity of the diseased kidney as well as of the urine and the urea and creatinin content of the blood.

In the writer's view, it is no less important to the welfare of the sufferer from chronic Bright's that the metabolic processes be watched than to protect by an appropriate diet the chronically "sick" kidney with a view to maintaining, as far as possible, its functional equilibrium.

Drugs.—Drugs, while not curative, may counteract certain dangerous tendencies resulting from interference with kidney excretion. In the exudative variety, in which anemia is often pronounced and progressive, a chalybeate course, from time to time, is useful. In this form, anasarca is also present and calls for treatment. The patient should be put to bed, where he should remain until the circulatory equilibrium is restored, while, at the same time, cholagogues, diuretics, and diaphoretics should be given.

Saline cathartics, exhibited after the Matthew Hay method, *e.g.* in concentrated solution in the early morning, so as to produce two or three watery discharges daily, are useful. Mercury, in all of its forms, is to be omitted, since it has been shown that this drug has a selective affinity for the kidney and is, therefore, harmful in its effects in Bright's disease. Unfortunately, the custom of prescribing a mercurial preparation at intervals in this complaint, especially when edema is present, is only too common, but it should not be approved by the medical profession.

Again, one of the main aims of treatment is to spare the renal epithelium irritating substances, hence such diuretics as caffeine, theophylline, sodium-acetate, and other members of the purin group should be abandoned in the therapeutics of this disease. On the other hand, we may employ for their diuretic effects, unirritating substances such as digitalis and the salts of potassium, especially the citrate, either singly or in combination.

Active diaphoresis, especially if induced by means of hot water baths, or hot, wet or dry packs, is a potent factor in lessening dropsical transudates and the albuminuria, if persistently carried forward at intervals of twelve or twenty-four hours.

In cases in which the renal lesions have not reached an advanced stage, the writer has observed excellent results from a course of the hot Nauheim baths, which markedly enhance elimination through the skin and kidneys.

The Karell diet, or the Karell cure, is warmly advocated by Goodman[6] and others. The technique is simple: "The patient receives daily at 8 and 12 A. M., and 4 and 8 P. M., 200 c.c. of raw or boiled milk, warm or cold, according to the taste." If great complaint is made of thirst, the patient may be allowed to rinse out his mouth with water, with instructions, however, that none be swallowed. It is customary to continue this strict diet in cases of renal edema for a period of one week, after which it may be gradually relaxed.

No aspect of the therapeutics of Bright's disease has engaged the attention of the profession to so great a degree as that of the associated hypertension. The lesson has not been learned as yet when active interference with this ofttimes compensatory mechanism should be commenced. It is to be recollected that while high systolic and diastolic blood pressures are constant symptoms of chronic interstitial nephritis, if we except the arteriosclerotic kidney of the aged, the inflammatory parenchymatous form, so long as it is compensated, exhibits no increase of blood pressure.

Says Engel,[7] the theory that ascribes nephritic hypertension to the chronic parenchymatous variety of renal disease rests upon confounding it with cardiac hypertension. In approaching the question of the management of the symptom, it is well to keep in remembrance that in the renal type of high tension, including evidences of damage to the vascular system, an unfavorable prognosis appears to depend, as pointed out by Stone, upon the height of the diastolic pressure, to which rather than to the systolic, our closest attention should be given, since it should form a guide to aid our efforts to reduce high blood pressure. In view of the presence of a greatly increased diastolic pressure, myocardial exhaustion supervenes, resulting in decreased urinary output, and symptoms due to increased retention of urea, leading in some cases at last to a fatal termination.

On the other hand, cerebral deaths, due to the greatly augmented diastolic pressure, are more common than myocardial deaths. It follows as a natural corollary that by a reduction of the high diastolic pressure, we not only relieve such features as headache, vertigo, and so-called renal asthma, but also and more importantly, prevent rupture of the

*While from 80 to 100 gm. of nitrogen daily are required, it is often advisable to allow much less, even as small an amount as 5 gm. for a week or two.

cerebral arteries—an accident that often terminates life abruptly. This indication is to be met by the cautious use of nitroglycerin in ascending doses, beginning with 1 minim every three hours. In this manner we also relieve the heart of a serious strain, which is the result of a greatly increased tension and may lead to myocardial exhaustion. My experience of the use of hot baths in selected cases accords with that of Rowntree,[8] who states that a drop of 10 to 20 mm. often persists some time after a hot bath that results in a good sweat.

While affording therapeutic assistance to meet high tension, the effects upon the heart, the urinary output, and the urea and creatinin content of the blood must be noted. A too great reduction of the arterial tension, a prevalent mistake, is undesirable, being attended with danger of uremia and serous transudates owing to the resulting insufficient urinary excretion.

Myocardial exhaustion, which manifests itself in the terminal stage of cirrhotic kidney, with signs of cardiac dilatation, scanty albuminous urine, and anasarca, requires heart tonics and stimulants. Here digitalis has good effects; it improves the myocardial tonus and often decidedly increases the urinary output as to both fluids and solids for a season at least. With the digitalis, a small dose of nitroglycerin may be combined if the peripheral tension be high.

If, despite the treatment described above, definite uremic manifestations, more particularly vomiting, muscular twitching, convulsions, or coma, supervene, vigorous measures are to be resorted to with all possible expedition. Starvation for two or three days is advisable. Prompt venesection followed by the use of physiological salt solution given subcutaneously, 500 to 1,000 c.c., as recommended by Herrick,[9] often gives much temporary relief.

The writer has observed good effects from the subsequent employment of the Murphy drip method of administering this solution, preceded by colonic flushing. Free catharsis and active diaphoresis must be secured in the manner above described.

Inhalation of chloroform, or, what is often a useful and the writer believes an essential measure, in some cases at least, the hypodermic injection of morphine in doses of from gr. 1/6 to ¼, is to be employed, and repeated according to the indications of the particular case. White and Wilcox[10] have shown that morphine does good in Bright's disease, by diminishing the oxidizing functions of the body metabolism. The late Dr. LeFevre lauded chloral, and the writer has observed gratifying results from its use in half-drachm dosage thrown into the rectum at intervals as required.

Time and space do not permit of a full presentation of the treatment of all complicating conditions and symptoms in chronic Bright's disease, but those omitted from consideration here must receive attention in accordance with accepted therapeutic principles.

Kidney Organotherapy.—This method of treatment has recently received considerable attention, but it has not had vogue long enough to permit of a proper appreciation of its value. Sajous[11] claims that favorable results have been reported in about one-half of the cases of chronic nephritis in which kidney preparations have been tried. One may use a maceration, as have Page and Dardelin,[12] or, more conveniently, a tablet preparation. The dose of the latter is ten to fifteen 5-gr. tablets daily, preferably given between meals. Kidney preparations produce several effects of which the chief are three: (*a*) The prevention of uremia, (*b*) a reduction in the percentage of albumin, and (*c*) increased diuresis. It is not improbable that kidney preparations owe their stimulating effect upon the urinary output and their antitoxic power to an adrenal principle in organic combination.

Salvarsan has yielded encouraging results in cases of syphilitic origin. Perhaps the only prerequisite to a fair degree of success in the use of salvarsan or neosalvarsan is the selection of cases in the earlier stages of this form of nephritis, since no drug "can possibly restore destroyed renal parenchyma or transform fibrous connective tissue into secreting kidney cells."[13]

Surgical Treatment.—The percentage of cases in which surgery, *i.e.* incision of the capsule or cleavage of the cortex, serves a useful purpose is probably small, and it is gratifying to note that the ardent advocates of these operative procedures are far less numerous than they were a single decade ago. It is conceivable that a splitting of the capsule or mere puncture of the same will diminish abnormal tension and thus relieve pain which may be present. Moreover, for hematuria, more particularly if practically limited to one side, "the operation should be recommended, as it has been frequently followed by the cessation of the hemorrhage in chronic Bright's disease." (Newman[14].)

As a rule, the good effects of operation are only temporary, the result of an improved circulation which, however, cannot be long maintained. Surgical methods cannot modify the nature and progressive character of a chronic nephritis, cannot arrest no even appreciably retard the renal and arterial fibrosis and their mechanical consequences. Finally, no form of treatment is, in a real sense of the word, curative that has not for its main aim an amelioration of the toxemic condition present and the removal of etiological factors in particular cases.

ARE THERE SUBJECTIVE PAINS?

BY MEYER SOLOMON, M.D.,

CHICAGO.

IN this paper I have endeavored to answer a definite question which I have chosen as the title of the paper. Are there such things as subjective pains? The answer to this question means much to us from many viewpoints, purely scientific and practical (diagnostic and therapeutic). I shall not hasten to answer this question. Owing to the nature of the problem involved, considerable quotation of the opinions of others must, of necessity, be resorted to, but this, I am confident, will be excused if it but leads to clarification of the situation, and to ultimate solution of the problem at hand.

How the Term "Pain" Is Used in This Discussion.—When I use the term "pain" in this paper, I do not mean to refer to or to include states of so-called psychalgia or so-called painful mental states, such as depression, fear, anxiety, shame, sadness, and the like. Nor do I have reference to such uncomfortable peripheral experiences as pressure feelings, hot or cold feelings, tremulousness, itching, and their ilk. I am speaking of what we ordinarily refer to as distinct so-called physical pain —that acute condition which Sherrington so well describes as the psychical adjunct of an imperative protective reflex, and which we generally regard as being a subjective appreciation of a peripheral process, peripherally induced, of sensory origin, and of which we become self-conscious.

The biological function of the self-conscious recognition of pain-sensations and its manifold and marked advantages over mere reactivity without self-consciousness of the nature of the process, need not be dwelt upon at this time. True, pain itself is a psychological fact. No such thing as pain exists unless self-consciousness is there to perceive it.

Behan, in his excellent and very complete work, entitled, "Pain, Its Origin, Conduction, Perception and Diagnostic Significance," finds it extremely difficult to define this everyday pain that all of us know so well, and which all have experienced much too often. It is one of those fundamental, elemental things that defy definition. It has been described as the kind of sensation we feel when the skin is cut or burnt. Sherrington's description of pain as the psychical (which he had better call the self-conscious) adjunct of an imperative protective reflex is in harmony with Behan's definition, which is as follows: "Pain is distinctly a mental interpretation, and cannot be strictly defined. It is the interpretation of some abnormal and generally harmful process which is occurring in the organism. It cannot be classed as a sensation, but rather is the result of the perception and interpretation of sensation by the mind,"[1] or, as I should prefer to say, by the self-consciousness.

When speaking of pain, therefore, in this paper, it is the simon-pure, true-to-color, universal experience and recognition of certain peripherally induced processes to which I refer. For the purposes of this discussion it is not necessary that I give a review of the very important work on pain and its tracts of conveyance as worked out so beautifully by Head and his associates. Behan gives a good working summary of the practical conclusions arrived at as a result of this indefatigable and painstaking labor, and the original papers[2] themselves may be referred to, if desired.

Peripheral Causes of Pain.—Of course, all sorts of peripheral factors of a physical nature may be the initiating stimuli of pain. In fact, excessive stimulation of any kind (chemical, thermal, mechanical, electrical) may reach such a degree of intensity that it finally produces pain. The original seat of this stimulation may be anywhere along the sensory tract or system—the cutaneous terminals of the sensory nerves, the muscular and visceral sensory terminals, the nerve trunks, the posterior sensory ganglia and sensory roots, and the optic thalamus. Irritation of the sensory tracts of the cord and brain rarely cause pain, but generally only paresthesias, while direct stimulation of the sensory cortex produces no pain.

The peripheral processes that may be responsible for the evocation of pain are protean. Behan gives a splendid summary of the peripheral types and causes of pains in every region of the body.

Head has called our attention to what he properly calls "referred pains" of peripheral (visceral) origin. The viscera, under excessive stimulation or irritation, may produce pains in various parts of the skin or bodily surface, the pain being referred or transferred from the former to the latter location by nerve connections. That these referred pains have been and still are being overlooked and labelled "hysterical," "neurasthenic," "imperative," "psychic," or "imaginary" pains goes without saying.

In discussing the causes of local pains in so-called neuritis and neuralgia, after mentioning the now generally acknowledged fact that genuine neuritides are relatively uncommon, Dana[3] justly declares that the neuralgias are in fact as a rule nothing less than true local pains, of a certain distribution, and terminates his discussion with the final conclusion: "That 'neuralgia' as usually defined is a very rare disorder, and its diagnosis is to be made only after careful examination of muscles, bones, nerves, nerve centers, and sources of reflex irritation."

We must, then, take into consideration as the possible peripheral causative stimuli of local pains, all sorts of conditions which we are ordinarily too apt to overlook—toxic processes, arteriosclerosis, occupational fatigue, chronic focal infection, disorders of the joints, muscles, tendons, bones, etc.

Objective Central Pains.—Over and above all these causes of pain we have certain types of pain which are called "central" pains—pains of central origin. The term "central pains" is used in two different senses. In the first sense one refers to objective pains occurring as the result of trouble in the central nervous system, more specifically, the optic thalamus. But, as Gordon Holmes[4] points out:

"It must be remembered that Roussy originally pointed out, and his observations have been confirmed, that these lesions which produce spontaneous pains and the associated overreaction to affective stimuli lie in the lateral region of the thalamus, where they must interrupt the fibers connecting the cortex with the thalamus, as these pass from the internal capsule into the latter. And if

we assume that by so doing they remove a control which the cerebral cortex, the organ of discriminative sensibility, exerts on the thalamus, the center of the affective elements of sensation, there would result a condition of overactivity of the latter which must show itself, first by an exaggerated reaction to these elements; and secondly by the occurrence of affective sensation under conditions which are not recognized as naturally capable of producing it, and these sensations will consequently appear to be spontaneous."

This type of so-called central pain is, it is plain, no exception to the rule that pain is apparently always due to peripheral stimulation recognized by the self-consciousness as such.

So-called Subjective Pains.—The term "central pains" is used by others in still another sense. In this latter sense the authors using this term refer to pains subjectively induced. Some call them hysterical, neurasthenic, or imperative pains, others refer to them as functional pains, and still others label them imaginary pains. Let us use the convenient trade-mark, "subjective pains," to include those pains said to be induced by the patient himself. I do not refer to self-mutilation or exaggeration or simulation.

Since in the field of medicine such supposedly subjective pains are most apt to be found and studied by psychopathologists, let us see what some writers and clinicians of standing have to say on this point.

Dubois,[4] after stating, "It is wise to remember that pain is, in the last resort, a sensation which can only be perceived by the ego. It is a purely psychic phenomenon," follows this in the very next sentence with: "Just as we have the right to consider as psychical all troubles of motion which cannot be explained by organic lesions or by intoxication, so we may suspect the mental origin of a pain when by conscientious and repeated examinations we are unable to discover its cause." He adds a few illustrative cases.

Dejerine and Gauckler,[5] in their discussion of "genital algias," assert: "The *thought* (italics mine) of physical malformation, painful coitus, a rather profuse leucorrhea, a real but temporary lesion, may be the origin of the psychic fixation of a painful symptom which, whatever its source, ends by being a pain of purely central causation." And again, in their consideration of what they call "thoracic algias," they say: "The false pulmonic, by reason of being examined and palpated, gets to the point where he discovers some peculiarly sensitive region. The mental representation of this pain projects itself in the form of a localized pain in the chest, accompanied occasionally by a cutaneous hyperaesthesia of the region where the pain is felt." Later on, in their discussion of subjective disturbances of sensibility, they speak of topalgias or what they also call "central psychic algias," as constituting practically the great majority of subjective disturbances of general sensibility described by various writers as occurring in the course of the psychoneuroses, and mention the possible locations of these pains (and they here include disturbances of visceral sensibility), finally to tell us that "The majority of these phenomena come about through the psychic fixation on the part of the patient of some pain that had once been experienced or some emotional sensation which had once been felt," adding, on the next page, that "Sometimes there seems to be no starting point, and the pain is created wholly by suggestion." They continue on the page after this to speak of "central pains," by which they mean subjective pains; and a few pages further along, in their discussion of the special therapy of these pains by stoical contempt, they make this statement: "All *pains of phobic origin* (italics mine), due to fixation of the patient's attention on some point of his body, and by the subcontinuous (subconscious is probably meant) calling forth of a pain whose cause has long since disappeared, may be treated in the same manner."

In contrast to these specific expressions of their belief in the possible ideational origin of localized pains, we find the following views thrown in with other statements and leading them to attribute such pains as are here described to the triple influence of emotion, suggestion and education: "There is no question that one may succeed by focusing the attention, even though it be more or less complicated by phenomena of imitation and suggestion, in educating a visceral or peripheral sensibility in just the same way as a blind man or a clever artisan educates his tactile sensibilities. But these facts ought to be put in the group of hyperesthesias rather than in the list of purely objective disturbances of sensibility. They are in fact phenomena of localized hyperirritability, which may be compared in their own particular domain to the diffuse hyperexcitabilities which we have already studied." The last sentence, although at variance with what goes before, is one with which we can not help agreeing.

Prince[7] has included pains under so-called hysteria. Freud,[8] in his presentation of "The Case of Miss Elizabeth v. R.," speaks of her pains as being symbols, by conversion of painful experiences or memories which have been repressed into the storehouse of the subconscious and subsequently forgotten, as the means of terminating or solving a disagreeable mental conflict. At one point he says: "The ideas of 'defense' (abwehr) against an unbearable presentation, the origin of hysterical symptoms through conversion of psychic into physical excitement, the formation of a separate psychic group by an arbitrary act, leading to the defense—all these were in that moment palpably presented before my eyes."

One finds, on carefully reading the report of this case, that, as, in fact, Freud himself admits, the pains complained of by this patient were fatigue pains of an indefinite nature, and the skin and muscles were especially sensitive (hyperalgesic) to pressure and pinching.

Others, following in the footsteps of Freud, have explained similar cases in like fashion. For example, Moyle[9] reports a case of a woman with severe attacks of pelvic pain with no discoverable physical cause, and sums up his view of the case in these words: "Frankly, then, this pain seems to represent a continuance of an accidental experience ('a single attack of pelvic pain occurring late in her convalescence from confinement'), or the exaggeration of discomfort from ptosis, through an unconscious elaboration into a justification for her life of invalidism."

Kempf,[10] in an interesting paper, giving the report of a patient who, among other symptoms, showed urticaria and itching, but without pains, in discussing Freud's views of the case of Miss Lucy R. (also reported in the same monograph in which is included "The Case of Miss Elizabeth v. R."), who apparently developed the persistent olfactory image of cigar smoke, and on comparing it to the findings in his own case, truly says: "Just how Freud understands that excitement may be converted into a physical innervation is not intelligible. Furthermore, it seems to me that this conversion conception is the keystone of Freud's important, but not quite satisfactory, libido concept." A critical analysis of this aspect of the problem cannot be entered upon here.

Diller,[11] in speaking of pains of "severe character, intermittent, remittent, constant or paroxysmal, dating back over a period of many months or many years," declares: "Such pains, I am firmly convinced, may constitute the expression of a morbid psychic state. Whether we call such pains hysterical or not does not particularly matter, but that they originate in the mind of the patient, and not in the knee, or abdomen, or back to which they are referred is the principle thesis of this paper." He refers to these pains as instances of "psychic pain, pain due to an idea, a mental operation." As means of recognition of these peculiar pains, he mentions two kinds of evidence: negative and positive. As negative evidence he finds that the pain does not conform to that of any one organic disease, and "seems too contradictory in time, appearance, duration and in many other ways features to indicate organic disease," nor can any physical disease be discovered after painstaking examination. As positive evidence, he mentions the influence of suggestion, and the fact that the patient tells the story in great detail, dramatically, showing that he has centered his life about the pain.

Fry,[12] after stating that "each of the several fundamental psychopathic tendencies presents a psychic reaction to pain which is destructive," and after enumerating the pains in the so-called hysteric, hypochondriac, neurasthenic and paranoic, finally gives consideration to the pains in the obsessive or psychasthenic, and calls them "imperative pains."

Janet and Sidis nowhere, so far as I can find, speak of subjectively induced pains. As I shall show later, by quotations from Sidis, he would agree at once with the thesis which I hope to prove before ending this paper, namely, that there are no subjectively induced pains.

Behan,[1] in spite of his prolonged study of the problem as evidenced by his very exhaustive and complete work on this single topic of pain, feels himself justified in asserting: "I shall also point out that the intellect can, by the exercise of memory, recall to mind the objective sensations classified as pain, and, by making them pertinent to the moment, cause them to appear real, as if experienced at the time. In other words, intellect is able to produce, without any objective means, the sensation of pain. The class of pain sensation which seems to appear without any definite causative factor, is frequently called subjective pain." And Behan then tells us that he believes in the reality of subjectively induced pains.

Dana[13] discusses the general subject of pain, from the standpoint of a neurologist, in an interesting contribution. He first lays down the law or doctrine of parallelism, concluding that "it must be apparent that all pains and all suffering are real things. There is no such thing, strictly speaking, as an imaginary pain; that is, a pain which has no morbid neural condition underlying it." In his discussion of what he calls "psychic or attention pains," he refers at one place to the pain in a certain obsessive patient being "central and would ordinarily be called 'imaginary' or hallucinatory," but he explains it as follows: "There was a disorder of attention and a lowering of the threshold of consciousness; all the time there was some real neural irritation which occupied and morbidly enlarged the field of attention."

Dana enumerates the following types of pains met with amongst psychoneurotics: (1) neurasthenic pains and pains in the constitutionally inferior, which he justly attributes to peripheral causes in individuals with cerebral and spinal centers that are weak, irritable, easily exhausted and tired, upon which, as a basis, attention pains may be superimposed; (2) the pains of obsessives, true psychic or attention pains, which Fry, as mentioned above, in a later article, called "imperative pains," and which occur in so-called psychasthenia; (3) depression and anxiety pains, occurring in hypochondriacal, depressive cases.

I quote Dana at great length in order to herewith present his attempt to explain the origin or modus operandi of these types of pain: "If one were to interpret these sensations psychologically, . . . I should say that in the psychasthenic pains there has ceased to be any peripheral irritation. The neuritis is gone; the nerve injury is healed, and the only neural disturbance is a morbid change in some primary sensory center, like the optic thalamus, where sensory impressions are first received and distributed. In other words, there is slight or no disorder of the sensory nerves, but there is some disassociation and disorganization in the work of the higher sensory mechanism. But beyond this, there has occurred disorder of attention; the patient's mind has become so fixed on this slight neural change that the threshold of consciousness is greatly lowered; and even slight neural disturbance keeps up an agonizing suffering. I would still insist that there is a neural change, and that the pains are not imaginary, but the neural disturbance is always a minimum, while the focusing of attention on it is at a very morbid height.

"On the other hand, in pains and dysesthesias that go with the anxious depressions, there is probably present a real morbid condition affecting perhaps especially the protopathic nerves. These usually do not arouse sensations in consciousness, but through conditions of autotoxemia, arteriosclerotic and the rheumatic and bad metabolic conditions that usually accompany the period of involution, these nerves are irritated. In addition to this, the mind of the patient is depressed by his psychosis and made more sensitive and attentive to the inflow of sensory impulses. There is then both an increase in the stimulus and a lowering of the threshold of consciousness."

Yet we find that the last sentence but one of his

article is somewhat in confliction with the above declarations, for we find Dana remarking: "There is not yet any simple test by which we can tell surely *when a pain is not a real, but an attention or habit pain* (italics mine)."

Sherrington speaks nowhere of possible subjective pains and assumes with right that all pain is of objective origin, although subjectively appreciated. He says: "Thus, physiologically the stimulus which excites these end-organs must, whatever its physical or chemical nature, possess, in order to stimulate them, the quality of tending to do immediate harm to the skin. Further, the reflex they excite (1) is prepotent; (2) tends to protect the threatened part by escape or defense; (3) is imperative; and (4) if we include psychical evidence and judge by analogy from introspection, is accompanied by pain.""[14]

Attempted Explanations of So-called Subjective Pains.—I have already enumerated the attempted explanation of a number of different writers who have believed in the occurrence of true subjectively induced pains. Many insist, without further explanation or qualification, that there are imaginary pains, by which they mean pains actually felt, but directly of purely ideational origin.

Behan, although contending that there is always some neural change produced, even though it be only central, which is responsible for the pain, still speaks of subjective pains in about the usual manner, although, like many another, he would deny that there are any true "imaginary pains," for either the patient has the pain or he has it not. Yet, if he has real pains which do not seem to be peripherally induced, he would not hesitate to classify them as subjective pains, centrally induced.

After these many quotations, I shall return to the question which I put before myself in the title of this paper: "Are there subjective pains?"

Evidence in Support of the Existence of Subjective Pains.—The evidence in support of the actual existence of subjective pains which has been offered by different authors interested in this question, include pains said to be due directly to hypnosis, pains occurring in the psychoneuroses, emotional pains, habit pains, monomania pains, pains found in the occupational neuroses, pains said to be the result of dreams, and, in general, ideational pains. Let us consider these topics briefly.

So-called Hypnotically Induced Pains.—It is said that by hypnosis it is possible to bring into the patient's self-consciousness the perception of real pain. Now, it is well known that many marvels, far beyond the facts, have been attributed to the power of hypnotism. Among the most common of these are hallucinations of all sorts. And yet, after a study of this very problem, by Boris Sidis,[15] one of the foremost, most trustworthy and most brilliant students in this field, the conclusion is reached that "*hypnotic and post-hypnotic suggested hallucinations are not genuine, but are essentially spurious; that hypnotic hallucinations, unlike actual hallucinations, are not really experienced; that hypnotically suggested hallucinations are only forms of delusions.*" (Italics Sidis'.)

Hugh Crichton Miller,[16] not aware of the conclusions of Sidis in this respect, quotes Moll, who speaks of subjective pains in these words: "Such 'imaginary pains' have been excellently compared with hallucinations. Now, we can say that the hallucinatory object is imaginary, but it is false to say that the perception is imaginary; it has a central cause, whether the object is imaginary or not. Similarly a pain that is felt is the result of a definite central process. It is a matter of indifference whether the central process is caused by a peripheral one, such as a prick, or by suggestion by a spontaneous mental act. The pain exists in both cases, and is not imaginary." As I shall show before I get through, ordinary hallucinations, like pains, are always peripherally induced, directly.

Psychoneuroses and Pains.—From what I have already said, with the many quotations from different clinicians, earlier in this paper, it is apparent that when pain cannot be attributed to peripheral processes or objective causes, it is not infrequent to see it pigeon-holed as subjective or central. It is, therefore, only by exclusion, or rather, when one cannot find any other cause for it or does not know what its real cause is, that one finds a pain being looked upon as subjectively induced.

Most writers agree that such subjective pains are actual or real pains, although brought on by ideational processes, or, as Behan would put it, by "the power of transferring sensation from the warehouse of past experiences to the mart of present change."

The attempt to prove such pains to be symbols, by "conversion," of painful psychic experiences or memories which have been repressed into the subconscious, is simply based upon the assumption that such pains of subjective origin can actually exist. Hence we are face to face with the fact that it is the latter question which is fundamental for consideration.

If it is impossible to produce pains by hypnosis, as is plain from what I have said under the heading, "So-called Hypnotically Induced Pains," or even in dreams, as I shall prove below, how much more impossible is it to expect such pains to be produced by ideas in the waking state of any person! Hence ideas, whether by suggestion or fixation of attention or what not, cannot produce pains, in the apparently normal or in neuropathic or psychopathic individual.

Emotions and Pains.—Pain, we are told, may be produced as the result of emotions—in great anger, sorrow, fear, and the like. Although in most cases this is not real pain of the ordinary kind, but rather a feeling of unpleasantness, nevertheless the feeling thus produced is an actuality, and in some cases emotional upset may really lead to pain. But how is such pain possible as the result of emotional upset? It is by the intermediate production of certain peripheral changes, such as spasms, as in angina pectoris. One sees clearly, then, that in these cases the pain is of peripheral origin, the peripheral changes being induced by emotional upset. Thus the emotional disturbance is accompanied by certain peripheral processes which in their turn may produce pain or other disagreeable peripheral, local manifestations. This sort of pain is not in opposition to the thesis here maintained, which is, that pain is of peripheral origin in all cases, and that purely subjective pains do not exist.

So-called Habit Pains.—Behan describes these pains in the following words: "This is the name

given to that great class in which the pathways for pain have been so grooved from frequent repetition that on the least provocation the stimulus travels over them and gives rise to a pain sensation."

What I have already said is sufficient to lead us to the conclusion that there are no such things as habit pains. Either the pain is kept up by certain irritating peripheral changes, or there is no real pain present.

So-called Monomania Pains.—Behan cites Brissaud in support of these so-called monomania pains, by which is meant a pain recurring as a habit at a certain time or in connection with certain objects. Brissaud believes that patients suffering with such pains are in fact suffering from an obsession, and that they have a delusion of pain when none exists. Behan adds: "If Brissaud means that they really have not pains, but delude themselves into believing that they have and act as if they had, and that the whole business is a delusional state, then we can at once agree with him." In that case, then, there are no so-called monomania pains.

Pains in the Occupation Neuroses.—Walton, cited by Behan, mentions pain induced only by making certain occupation movements and not invariably produced even then. We can dispose of these at once by declaring unequivocally that either such patients have real pains or they have not such pains. And when pains do exist, they are due to definite, peripheral, local, provocative factors of one sort or another.

Dreams and Pains.—In his work on pain, Behan informs us: "In the dream state, also, vivid sensations may occur." And by this he means that pains may occur in dreams, as a result of the ideational processes in the dream.

I know of no one who will assert with absolute positiveness that true pains have ever been brought on in dreams as the direct result of the dream ideas themselves, and this, in spite of the fact that in dreams, as Freud mentions, we descend from the thought level of mental imagery to the sensory perceptive level of mental activity—from concept to percept, from idea to sensation.

The so-called toothache and headache dreams, and the like, are, in truth, dreams in which one has a real toothache existing independently of the dream, brought on by peripheral processes and woven into the dream as such; or, no real toothache or headache is present, but the dreamer merely has an idea of the same, and thinks about it *as if* he were having a pain in the tooth or head.

Freud[17] himself, in his Interpretation of Dreams, in disputing the somatic source of dreams, says: "I can perceive a sensation during sleep through and through sleep, as it were, which happens as a rule with painful stimuli, but without weaving the pain into the texture of the dream." He nowhere, so far as I can discover, considers the possibility of pains occurring as a direct result of the dream thoughts.

We may, with assurance, it seems to me, declare that it is impossible to experience actual pain in sleep as a result of dreams, unless there is real, peripherally induced, local pain present—toothache, headache, furunculosis, etc., etc. Our discussion to follow, of supposedly ideational pains, will give the reason for this.

Ideas and Pains.—The receptive apparatus for pain is not yet well defined, but we do know that the existing sense receptive organs for pain are widely diffused, and are capable of receiving pain stimuli of various kinds (such as touch, deep pressure, heat, cold). The terminal filaments in the skin have been called nociceptors by Sherrington, who has shown that those parts of the body most subject to injury in phylogeny (evolution) have a more numerous supply of nociceptors than those not so exposed. Crile[18] has done much to develop this point of view at great length.

The pain-conducting apparatus consists of the nerve fibers from the periphery to the sense-perceptive centers. The primary pain center is supposed to be in the optic thalamus. The cortex has an inhibitory and controlling influence over the thalamus, as Holmes believes. The cortex itself, be it repeated, is insensitive, although attempts have been made in the past to localize pain perceptive centers in different areas of the cortex. Pain, then, is a special type of sense-perception.

In consideration of the relationship of ideas to pains, we are in the same position as we would find ourselves in discussion of the general topic of the relation of ideas to other peripherally induced processes—smell, hearing, taste, vision, and all sorts of haptic phenomena, such as feelings of warmth, of coldness, of pressure, and the rest. This leads us to the general problem of hallucinations. Pain is the self-conscious recognition of a definite kind of peripheral sensation.

We must ask ourselves the question: Can an idea evoke a sensation, directly? Observe yourself, analyze yourself, study yourself, and you will at once hit upon the truth. The answer is emphatically "No."

No one has put this better than Sidis, whom I shall permit to answer this question for us, from various angles.

Sidis[19] says: "The image of a light does not shine, the idea of a voice does not sound, and the representation of a perfume does not smell. A sensation, or presentation as it is sometimes termed, differs from an image or representation qualitatively, fundamentally. The sensation or presentation is given as immediate experience, while the image, the representation, is essentially mediate, it is a mental substitute for the immediate experience of the sensation. The idea or image bears the same relation to the sensation as a photograph bears to the original, or rather as a symbol to the thing it represents. Ideas, images, representations, substitute, represent sensations, but they are not sensations. A sensory process is fundamentally different. A sensation is not an intense idea, nor is an idea a weak sensation. Ideas differ far more qualitatively from sensations than visual sensations, for instance, differ from olfactory sensations. There is not a particle of evidence to substantiate the view that ideas or images are copies of sensations in the sense of being weak sensations or 'centrally excited sensations.'"

Again, in his differentiation of ideational from perceptual processes, he writes:

"Ideational and perceptual processes cannot be identified. The two are qualitatively different: the sensation has intensity, the image lacks it. We

may point out the main differences of sensation and image. (a) A sensation has intensity, an image totally lacks it. (b) An image is a reproduction or, rather, a representation, a symbol of a sensation, but no sensation represents another; a sensation, unlike an image, is not mediate, but immediate experience. (c) A sensation bears the mark of externality, an image lacks it. Finally, (d) a sensation cannot be called up at will, while an image is independent of peripheral stimulations of external objects, and is usually under the control of the will. No sensation differs so much from another as the image differs from its corresponding sensation."

Subjective pains may be said to be hallucinations of pain. Sidis insists, and I believe he is unquestionably right, that an hallucination is a percept and is essentially sensory in character, and remarks: "Ideas and images are not possessed of magic virtues, and with all the fancy work about them, they cannot display sensory qualities."

In his elaboration of the question of the primary and secondary sensory elements, he states: "The primary elements are initiated directly by incoming peripheral stimulations, while the secondary sensory elements are brought about indirectly, through the mediacy of the primary elements, the secondary elements themselves being really derived from sense-organs other than the ones directly stimulated by the peripheral excitation." But even here, to be sure, the secondary elements are of peripheral origin, the sense-organ being indirectly excited by a peripheral stimulus which primarily arose elsewhere. However, there is no evidence to prove that pain may be evoked as a secondary sensory element. We must surely agree with him when he specifically maintains that *there is memory for images, but not for sensations.* His contention that hallucinations are real and objective because of the constituent sensory elements chimes in with all that has been mentioned above.

We need not summon to our aid any further evidence for the conclusion that *an idea of a pain can by no manner of means evoke a pain.*

General Remarks.—One must differentiate a generally sensitive or irritable nervous system, with a generalized hyperesthesia for all peripheral sensations, from true pains. It is true, however, that persons with irritable and impressionable nervous systems feel pains more readily and acutely than individuals with relatively stable nervous systems. There may, thus, be pains in a patient otherwise or also neuropathic or psychopathic.

Simulation, of course, cannot produce pains, unless self-mutilation be resorted to. Unsatisfactory or false descriptions or interpretations by the patient may lead to the description of certain peripheral feelings as pains, although no actual pain is in reality experienced by the patient.

Exaggeration must be excluded.

Delusions of pain must be clearly differentiated from true pains.

The referred pains of head must be thought of in certain cases. How often they occur and how we can positively prove their origin it is difficult to say.

Nothing said throughout this paper should in any way lessen our faith in the value of a stoical attitude in life, and in the good to be obtained by psychotherapy and distraction in the relief or minimization of actual pains by heightening the threshold of consciousness, with blocking or repression of the pain.

Conclusions.—All pains are peripherally induced and subjectively appreciated.

There are no subjective pains of primary central origin.

Ideas cannot directly produce pains.

When, as a result of cross-examination of a patient, real pains are found to exist, look for a peripheral cause of some sort or other. The peripheral factors responsible for the production of pain are protean.

HOSPITAL SOCIAL SERVICE IN NEW YORK.

By N. GILBERT SEYMOUR, M.D.,

NEW YORK.

DIRECTOR GOUVERNEUR HOSPITAL TUBERCULOSIS CLINICS, CHAIRMAN SOCIAL SERVICE COMMITTEE.

A DESCRIPTION of the development of any form of social service may properly begin with a definition of terms. The phrase is now applied to such a range of activities that definitions will serve at least to make clear the meaning of the writer even though they fail to fulfill any other requirements.

The term "social service," as it is used to-day, may be defined as the practical application of the ideals of chivalry to the conditions of modern community life. It represents the conscious effort of the stronger to help the weaker, of the more fortunate to help the less fortunate, and, in the aspect with which we are chiefly concerned, the effort of the well to help the sick.

No better examples of general social service can be given than the work of our neighborhood settlements here in New York, of our institutional churches and synagogues, and of our great charitable societies. These organizations seek to render service to their neighbors by providing a better environment and wider opportunities. They aim to make their beneficiaries happier people and better citizens; but they deal, to a large extent, with well people or with individuals whose problems are not complicated by ill health.

Medical social service is obviously that branch of general social service which deals with the social problems caused by, or complicated by, illness. How closely it is connected with general social service is evident when we consider the relation of poverty to disease. It is hardly possible to render social service in a modern community without constantly employing some form of medical social service.

Medical social service is not a recent development. It is essentially as old as the practice of medicine. Wherever, among those who have cared for the sick, there has been the impulse to treat the patient as well as the disease, there medical social service has been rendered. The parable of the Good Samaritan provides a perfect example of such service, for the traveler not only bound up the wounds of the man who had been set upon by thieves, but also provided for his after-care. The development which is recent in such service is its recognition and organization. What was left for centuries to individual physicians and nurses with enough of vision to see the need and enough of personal initiative, or of opportunity, to meet it, has, within a generation, become a recognized factor in the diagnosis and treatment of disease. Once recognized as an accessory to modern treatment, it was both logical and inevitable that its organization and standardization should follow, and, as a result, there has developed a highly specialized, technical form of medical social service, adapted specifically to the treatment of disease and organized as a distinct department of our medical institutions. This is hospital social service as we know it to-day.

It will be seen that the definition given to general social service will apply to its specialized branches; but where the problem of the individual to whom service is rendered is caused or complicated by ill health, there medical social service is applied. Where the illness or ill health is the sole factor, or the chief factor, in the situation, the type of social service to be rendered becomes at once more technical, and this is the specific field of hospital social service.

It is apparent that the distinction between medical social service and hospital social service is one of degree only, depending upon the emphasis laid upon ill health in the problem of the individual or family under consideration. Frequently the province of one invades the other, as the illness assumes a graver or a less serious aspect. Conceivably a patient first in need of hospital social service later comes within the province of medical social service, as his illness recedes, and ultimately is a candidate for social service without medical technicalities, when, for example, the physical handicap has been removed and our neighbor is wrestling solely with an economic situation. The only value in the arbitrary distinctions between the form of social service rendered lies in the delimitation of territory for the persons rendering it, in the possibility of efficient coöperation and the avoidance of duplication of work.

There is a further advantage in such a delimitation and that is the standardization of qualifications for workers in these various types of social service. There has been so much discussion of these qualifications and of the relative importance of so-called social training as compared with medical (hospital) trainng that the subject merits especial emphasis. Contrary to the opinions expressed in some other cities, it is the conviction of those who have studied the situation in New York that whereas social training is highly valuable, medical training is absolutely essential for intelligent medical social service; and that for our hospital social service departments graduate nurses only should be eligible as salaried workers. This viewpoint is the result of experience with conditions as they exist in New York and with the development of the work here. They will be discussed later.

Before describing the origin and growth of hospital social service work in New York, it is proper to outline its earlier development elsewhere. The earliest systematic hospital social service recorded was the attempt made, in 1791, by Sir William Blizzard of the London Hospital, in Whitechapel Road, to follow the patients into their homes for the purpose of remedying conditions and providing for suitable after-care. This he endeavored to accomplish through the assistance of volunteers who made home visits under his supervision. This was an isolated effort of an individual with vision.[1] For nearly a century no other hospital imitated this inspiration, although there is a record of medical social service rendered by the Boston City Dispensary in 1806.[2]

In 1880, in England, an organization with the

amazing title "Society for After-Care of Poor Persons Discharged Recovered from Insane Asylums"[3] was established in connection with institutions for the care of the insane. In so far as these institutions were considered hospitals, this organization must be noted as an early example of hospital social service. The effort thus made to follow up mental cases discharged from institutional treatment was imitated by our State Charities Aid Association which, in 1905, undertook, through official visitors and volunteers, to supervise the home care of such patients.[4]

In 1890, C. S. Loch of the London Charity Organization Society made an important contribution to hospital social service by his suggestions for the reorganization of the "lady almoners," already associated with many English hospitals.[5] The plan thus outlined was submitted to a committee of the House of Lords in the same year. The first lady almoner under this plan was appointed in 1895, at the Royal Free Hospital in London. Her qualifications and duties are described in the *British Medical Journal* (February 5, 1910).[6]

Baltimore was the first American city in which a definite effort was made to secure recognition by the medical profession of the importance of systematic medical social service. It had long been recognized that there are factors in disease which drugs and surgery alone cannot eliminate—factors of temperament, of environment, of circumstances; in a word, *social* factors—which had acquired an increasing significance in the study of diagnosis and treatment. These factors were deemed of such importance by Dr. Charles P. Emerson of Johns Hopkins University that, in 1902,[7] he secured the coöperation of the local Charities Society in sending medical students to visit families in their homes, to study at first hand the social causes of disease. In describing this contribution to medical social service, Miss Cannon says, "Dr. Emerson's valuable work differed from the present social service in hospitals in that he was aiming to eduucate medical students, not primarily to serve hospital patients. His students visited many who were not sick and paid no especial attention to the clinics."[8] Unfortunately, this valuable experiment was discontinued, after several years, as it was thought to take too much time from more technical and, inferentially, more important work.

No further advance in the development of hospital social service was made until 1905, when Dr. Richard Cabot of Boston secured official recognition for a medical social service worker, Miss Garnett I. Pelton, a trained nurse, in the Out-Patient Department of the Massachusetts General Hospital. That was the beginning of a movement which grew at first gradually and through isolated efforts, and later with amazing rapidity, into the officially organized social service departments which are found in all well-equipped hospitals to-day.

The first organized hospital social service department in New York City was established at Bellevue Hospital in 1906. For many months there was but one social worker, Miss Mary E. Wadley, a trained nurse, who built up, single handed, the social service department of an institution with a daily census of over one thousand beds. Under her leadership there has grown a department, now comprising subdivisions, with forty-five salaried workers and auxiliary committees numbering over one hundred and fifty men and women. The spirit of hospital social service in New York is in large part due to the courage, vision, and personality of Miss Wadley of Bellevue. The social service departments of our other hospitals have been modeled, more or less, on the standard set by Bellevue; and Bellevue, under Miss Wadley, remains the leader, as it was the pioneer, in hospital social service in New York.

Prior to 1906 much excellent medical social service had been undertaken by the tuberculosis and other clinics, the nurses' settlements, and visiting nursing associations. Notable contributions to this movement were made by the Nurses' Training School of the Presbyterian Hospital, under Miss Anna C. Maxwell, and by Dr. Henry Dwight Chapin at the Post-Graduate Hospital.[9] This type of medical social service represents the function of the visiting nurse rather than that of hospital social service as we have defined it.

A feature of the work here which is distinctive and has had a marked influence upon its development in New York is the fact that it was started in the wards of our hospitals rather than in the out-patient departments, and has only gradually and recently invaded our dispensaries. In other words, hospital social service in New York has grown centrifugally, from within outward. It began at the heart of the hospital and has only gradually reached its extremities. This development has had a significant effect upon the attitude of the hospitals in New York to their social service departments, as well as upon the attitude of the departments toward their work. Here, from the first, the emphasis has been laid upon the technical, medical aspect of the problem, and the social elements in each case were viewed in the light of their bearing upon the diagnosis, treatment, and the prevention of recurrence. It is at once apparent why it is so strongly felt in New York that the hospital social service worker must be a graduate nurse. Only a nurse understands the routine and vernacular of the hospital. The necessary technicalities and red tape hold no mystery for her. She is familiar with it all. She is *persona grata* to the medical staff and nurses because she speaks their language and understands their viewpoint. To her, with the least possible expenditure of time and effort, a technical problem can be explained, and she can make an intelligent contribution to its solution through the social data, interpreted in medical terms, which she is able to collect. To the patient, unaccustomed to the hospital atmosphere and routine, she is the "friend at court." She is able to interpret the hospital to the patient and able to interpret to the patient the mysteries of the hospital.

It should go without saying that no amount of training, either medical or social, will make a successful worker of a woman without tact, sympathy, untiring patience, and the saving grace of humor. A thorough groundwork of social training will save much wasted effort and many needless mistakes in "social diagnosis" and "social treatment." But though she have all these things, if she has not hospital training, she cannot, in our opinion, become the ideal hospital social service worker. In ordinary medical social service, perhaps less tech-

nical training will answer reasonably well. Certainly that is the opinion in some other cities. In hospital social service, never. That is the consensus of opinion here.

Very recently a most interesting development of this idea is the plan of providing a course at Columbia University for graduate nurses desiring positions in the social service departments of hospitals. This course will be given under the joint supervision of the Department of Public Health Nursing at Teachers College and the New York Conference on Hospital Social Service, the college providing the theoretical work and the social training, the Conference arranging for practical "field work" in the social service departments of the affiliated hospitals. A certificate, at the satisfactory completion of the course, would cover both fields, and a nurse with personal qualifications in addition would find positions open to her in any city in this country.

Reference has been made, in this connection, to the New York Conference on Hospital Social Service. This organization was formed at a meeting called for that purpose at the New York Academy of Medicine on January 25, 1912. It was the result of a series of informal conferences held by representatives of the social service departments of a number of New York hospitals for the exchange of experiences and suggestions in the problems common to their work. The Conference is composed of the trustees and other officials of the affiliated hospitals, representatives of their staff and medical boards, members of their social service committees, and finally the social workers themselves. The Conference is governed by a board composed of representatives of each group, (*a*) officials, (*b*) committees, (*c*) workers of the hospitals, enrolled in its membership. The routine business naturally devolves upon the officers, a smaller executive committee, and upon an executive secretary, Miss Mary H. Combs, R.N. The Conference holds four public meetings each year—in October, December, February, and April—which serve as a forum for the discussion of current problems. The Proceedings of the Conference are published annually. There are now thirty-six hospitals and dispensaries enrolled.

Among the interesting by-products of this organization has been the development of the cardiac work in New York, which originated in a discussion before the Conference, following a committee report, which was submitted in February, 1912, on the industrial training of cardiac cases. This led to the establishment of the Convalescent Home for Cardiac Cases at Sharon, Conn., where industrial training was given in addition to convalescent care, and the group of members of the Conference who conducted this experiment later incorporated their organization under the name of The Trade School for Cardiac Convalescents. This society maintains the Sharonware Workshop at 84 Lexington Avenue, where men handicapped by heart disease and previously engaged in laborious work are employed, under medical supervision, in an occupation suitable to their physical condition.

The success of this pioneer effort to meet in some part the immense cardiac problem—second, numerically, to the tuberculosis problem—and the recognition by the trustees of the Trade School that their special field, the laboring man, represented only a fraction of the problem as a whole, led to the organization of the Society for the Prevention and Relief of Heart Disease, incorporated in October, 1915, which serves as a clearing house for all phases of the problem. Under the auspices of this society, special cardiac classes are being organized in the dispensaries of many New York hospitals, and it is hoped that the city will eventually be districted, as it now is for the dispensary treatment of tuberculosis, and that an association of cardiac classes may render the same service to these classes that the Association of Tuberculosis Clinics now so efficiently renders to the district tuberculosis clinics. The Association for the Prevention and Relief of Heart Disease would stand in the same relation to such an organization as the Committee for the Prevention of Tuberculosis now stands to the Associated Tuberculosis Clinics; while the Trade School for Cardiac Convalescents represents the special care of a selected group of cases, much as a tuberculosis class, or the Home Sanatorium, cares for selected cases. Ultimately, it is hoped that similar organizations may be achieved in other cities and affiliated into a national association. Only by intensive work for small groups, and coöperation and affiliation of the larger groups, can we hope to solve this tremendous problem of medicine and social service.

In conclusion, two questions naturally suggest themselves to any one who has studied the situation here and elsewhere. (1) Why have the hospitals been so prompt to avail themselves of this form of public service, involving as it does a considerable increase in their operating expense? (2) Why have physicians, as a class, been so slow to recognize the need of such departments in their hospitals or to utilize them to the full, once established?

The answer to the first query is more obvious than that to the second. The organization of a hospital is, after all, a business proposition. Whatever makes for efficiency, the hospital is quick to appreciate and appropriate. The social service departments in our city hospitals have made for efficiency in treatment and economy in administration, despite the expense of maintaining them—an expense which should be promptly increased by the payment of adequate salaries to our social workers. They have made for efficiency by providing etiological data, not otherwise obtainable, which assists in making correct and complete diagnoses; by rendering treatment more effective through intelligent coöperation in the homes of the patients, and by adequate after-care. They have made for economy by reducing recurrences and securing the completion of treatment. Finally, they have rendered the hospital acceptable to the public, which is, in itself, a service of magnitude. The social service department is the shock absorber of the institution, serving as the intermediary between the patient and his family outside the hospital, on the one hand, and between the family and the hospital authorities, on the other. The amount of friction and time saved is incalculable—it is an economy of both money and energy.

It is not so easy to understand the indifference

or ignorance of the medical profession. To them has been due the inception of the idea of hospital social service and upon them devolves the responsibility for its success. Only one explanation seems reasonable. "Physicians are a conservative class, besides a very busy one. They are not apt to take up any new adventure unless they can see quite clearly for themselves the actual benefit of the method. In other words, they are not moved by the pure sentimentality which would appeal to the laity."[10]

Once let them be convinced of the value of hospital social service work in the diagnosis and treatment of their hospital cases, and the social service departments have no more ardent advocates than the medical profession. Of what use to prescribe a tonic and recommend a liberal diet to a dispensary patient who cannot benefit by the one because he cannot secure the other? How prevent recurrent decompensation in a cardiac case who goes to a home on the fifth floor or to a job as hod carrier? Of what benefit to recognize a migraine as the result of eyestrain, if the patient cannot afford glasses? How help the acutely ill patient whose symptoms are aggravated by worry over home conditions? What convalescent care can be given to the man whose family are starving while he is out of work? And if he goes without convalescence, how long before he will be back in the ward? How can the surgeon estimate the end results of his work unless he can have his cases followed up for weeks, or months, after their discharge from his ward? And this is true of more cases than the surgical alone.

To the patient and to the public the social service department in our hospitals means the humanizing of an institution, until from a place of mystery and terror it has become a refuge and a haven. To the officials it means increased efficiency and economy of routine. To the medical board it should mean a completeness of care and a thoroughness of cure never before possible under the old régime.

129 EAST SEVENTEENTH STREET.

When to Eat and How Much.—Bergonié has calculated that to get the best utilization of food one should eat at 7.30 A.M. the chief meal of the day, to consist of 1500 to 2000 calories. The second and last meal, consumed at 6 P.M., should comprise 1000 to 1200 calories. A heavy noon meal and a late evening meal, the author holds, despite the prevailing custom, are irrational.—*La Presse Médicale.*

SHOULD WE BE MORE CONSERVATIVE IN THE USE OF ARTIFICIAL PNEUMOTHORAX?*

BY JOHN ROY WILLIAMS, M.D.,
ASHEVILLE, N. C.

PULMONARY tuberculosis seems to have as many different treatments as "Carter had oats," and Carter is said to have had "some oats." We have nearly every possible form of treatment for this disease from a rational attack upon the cause of it, directly and indirectly, down to McDuffie's "garlic poultice." Somewhere in the list is found artificial pneumothorax, or lung compression, for which, by some, are being claimed the most wonderful results. .

The origin of the idea seems to be a matter of debate. Murphy[1] says, "the principle of organ rest was first conceived by Carson of Liverpool, in 1821, when he advanced the idea that a diseased lung would heal more quickly if the lung itself were put at rest. He published a paper in 1822, detailing experiments on animals in which he produced an immobilization of the lung by artificial, or rather, surgical pneumothorax." Tuffier[2] claims that Potain, in 1888, was the first to attempt it for therapeutic reasons. Sloan[3] attributes compression to Carson by natural hydro and pneumothorax, but gives credit to Forlanini, in 1882, for being the first to bring it about artificially by means of atmospheric air introduced into the pleural sack by a needle from without. Minor[4] agrees with Sloan, and disputes the right of the Germans to claim the credit for Brauer.

Murphy[1], in 1898, took up the work and, while he admits that Carson was the originator of the idea, states for himself and associates, "we take a pardonable pride, we hope, in seeing this method universally adopted, sixteen years after it was first advanced by us, as an effective treatment of tuberculosis." So, who is the originator of this treatment?

Carson believed that cases of tuberculosis which developed a hydro- or pneumothorax showed a tendency to a cure of the tuberculosis, and that it was due to a fixation of the lung. Spengler[5] later made the same claim; but Cornet[6] holds that Spengler's idea is not in keeping with the experience of most clinicians.

Artificial pneumothorax, according to Forlanini, is "putting an air-splint on the diseased lung." Sloan[3] says, "this is a mechanical treatment analagous to the application of the plaster cast to the broken bone to immobilize it." But is it analogous? I do not believe it is. Compression tends to bring about blood and lymph stasis in the lung, and the plaster bandage that would do that would be improperly applied, causing a condition that would soon necessitate its removal. The lung is very rich in blood vessels, most of which have the thinnest possible walls, and are very easily collapsible. When you compress an organ the size of the lung down to that of your hand, the circulatory disturbances which must follow hardly seem possible of being other than unfavorable to the

*Read before the Medical Society of the State of North Carolina, April 19, 1917.

health of the organ, or to a recovery from any disease which may be attacking it.

Bruns[7] says that at autopsy he found a compressed lung showing complete atelectasis, with stasis of the blood which remained venous. McKenon[8] reports the findings in an autopsied lung that had been compressed, showing a marked and peculiar congestion of the lung throughout. It was 6 inches wide, 2 inches thick, and extended from the dome of the liver to just below the clavicle. It was bound down by eight tense bands of adhesions, which doubtless prevented it being more compressed. Was that a cure, or was it, in effect, an extirpation of the lung?

In tuberculosis our efforts should be to cure the diseased portion of the lung, and save the remaining healthy portion. Murphy[1] has likened the operation to that for appendicitis. In that he may be correct. The appendectomy does not cure the appendix, it removes it. Compression, in a very large number of cases at least, may be analogous to the removal of a healthy ascending colon along with the diseased appendix.

Murphy[1] says that as soon as we find tuberculosis, we should immediately compress, just as when we find appendicitis we should immediately turn the patient over to the surgeon for operation. He advocated compression in the early cases; yet he says that Saugman reported 67 early non-complicated cases treated by compression, with only 17 cases well after a period of from sixteen months to three and a half years, which is a little less than 24 per cent. I believe that with hygienic, dietetic, and medicinal treatment, without compression, we are doing very nearly three times as well.

Murphy[1] says to compress the early cases, Sloan[3] to reserve the treatment for the more advanced cases. Others, and they are the majority of the compressionists, say do not compress until the patient shows no hope of recovery by all other means. Most compressionists claim it requires a knowledge and skill uncommon among physicians to select cases proper for compression. Judging from the differences of opinion as to which are the proper cases for compression, one may believe it does require an almost superhuman skill and knowledge.

As for skill. From all I have been able to hear and read, along with a limited observation, the operation seems a very simple one. The simplest surgical skill, combined with the specially devised apparatus for the purpose, is all that seems necessary to perform the operation. As for knowledge, if we are to select the incipient cases, possibly a highly developed knowledge is necessary. But if we are to select the advanced cases, or the seemingly hopeless ones, I cannot see where any special amount of knowledge is required.

Most compressionists say we should select the far advanced cases in which the disease does not extend down any further than the third rib in the other lung. Suppose we compress a left lung with an apical involvement in the right? The compressionists say "rest for cure," yet they seem willing to throw extra work upon this right lung which they hope to cure. Can we not expect, and most compressionists report it to be their experience, that the disease in this right lung will rapidly advance? I am pleased to find that Dunn[9], along with a few others, cautions against this. But even if that other lung is not diseased, which is a very rare incident in the far advanced cases, will it not more certainly become emphysematous, which is not only undesired, but is also dangerous to the right heart?

What are the dangers of compression? There is the so-called "pleural reflex," to which has been attributed sudden death by some. Grey[10] says there is no such condition, yet Sundberg[11] reports two deaths from it, and one death from spasm of the larynx probably caused by the pleural reflex. Displacement of the mediastinum has proven very dangerous in a number of cases. Considerable displacement of the heart, with marked interference with its function and a serious disturbance of the circulation, has been frequently reported.

Rapid evacuation of a compressed cavity has been reported as causing a spread of the disease to the other lung, with early death following. Pleural effusions are very common, occurring in not less than 60 per cent of cases, if not more, as reported by nearly all of the compressionists. There is often perforation of the lung, nearly always followed by septic infection, producing a pyopneumothorax with its consequent deleterious effects. There is danger of infection from without during the operation; and it is thought by some that germs will pass from the lung into the pleural sack without perforation, especially in those cases where a high positive pressure is used.

Air embolism is reported as being a more or less frequent happening, proving very dangerous and, in a number of instances, fatal. Forlanini[12] reports a case of miliary pulmonary tuberculosis following compression, complicated with pericardial effusion and death. There have doubtless been other similar cases which have never been reported. Acute general miliary tuberculosis, tuberculous pneumonia, and tuberculous meningitis have followed the operation, and by many are believed to have been due directly to it.

Lloyd[13] reports a case of pulmonary abscess which proved fatal, and which he was helpless to check. I can easily see how such a condition can be brought about. And pulmonary gangrene can easily follow, caused by the blood stasis in a lung that is infected by many pathogenic germs.

Diminished aeration of the blood, causing poorer nutrition, will produce a lower tissue resistance. There is also a general inflammation of both the visceral and parietal pleura, believed due to the irritation of the gas used, to disturbed circulation in the parts, and probably to infection in many instances.

The failure of the compressed lung to reexpand after the removal of the gas, and a complete adhesion of the visceral and parietal pleura after expansion, are both reported to be frequent occurrences. There is a marked and sudden interference with the pulmonary circulation, bringing about blood and lymph stasis, and greatly raising the blood pressure in the pulmonary artery. There is damage to the right heart, caused by the increased pressure it has to work against, by the pleural inflammation and adhesions, by the lessened aeration of the blood, and by the emphysema brought about

in the uncompressed lung. And this dangerous effect is brought about when already the right heart is handicapped by the disease before compression is resorted to. To my mind this seems a rather long list of reasons why we should be at least more conservative in the use of artificial pneumothorax. Are all of these dangers to be lightly considered?

Are all of the supposed good results of compression due to it alone? To quote Webb,[14] "two cases which refused the application of pneumothorax, and whose condition seemed hopeless without the application of this remedy; and two cases in which we were unable to induce it, are now in excellent condition, walking several miles a day and with almost complete absence of expectoration." Does not this experience justify the belief that many compressed cases would have done just as well without compression?

With compression it is claimed the fever is reduced, cough and expectoration diminished. Certainly the fever is reduced, for with the blood and lymph stasis, absorption is made almost impossible; certainly the cough and expectoration are reduced, for the lung is placed in a condition making drainage almost impossible after the initiatory collapse of the lung. But is that a cure?

Is it worth while to deprive the blood of its necessary aeration; to bring about blood and lymph stasis; to keep up a poorer nutrition, producing lessened tissue resistance; greatly to overwork an already overworked right heart; to give the other lung, which is so often already diseased, from half as much more to double the amount of work to do; to take a chance of bringing about an extension of the disease to the uncompressed lung, in order that we may reduce the cough and expectoration? Should we be willing to take a chance of bringing about air embolism, perforation of the lung with almost certain septic pleurisy with effusion, tuberculous pneumonia, tuberculous meningitis, acute general miliary tuberculosis, sudden failure of the right heart, sudden death from pleural reflex, or from spasm of the larynx, for the still unproved good results of compression in a still very limited number of compressed cases?

The reports of cases treated by compression are interesting, to say the least. They claim from 0 per cent. of cures to 100 per cent. They claim improvement in from 18 to 92 per cent. This seems a very wide variation in the results obtained, and justifies the belief that, at best, the reports are vague, ambiguous, and misleading.

The reports show some compressionists claiming no effusions in their cases, while others report 100 per cent. with effusions. Baldwin and his coworkers at Saranac claim 100 per cent. effusions in their cases. Peters believes that with time from 90 to 100 per cent. will show effusions. Bullock[15] claims to have had but one effusion in all his cases, and that one with a beneficial effect. He attributes it to the wonderful climate of that portion of the West in which he operates. This would seem to attribute an extraordinary virtue to climate, of which I have never heard before. You may remember that he is the man who claimed that none of us east of the Mississippi can point to a single cure of tuberculosis two years after discharge from treatment. He might be placed along with Marpham, who claimed to have grown dead tubercle bacilli in pure culture. It is a case of "he may be right, but I doubt it."

Hamman[16] says that after compression the lung very often fails to reexpand. Mannheimer[17] says, "We can never know whether the lung will reexpand. Sloan[18] says that "after reexpansion a complete fixation of the lung to the chest wall occurs in some cases from pleural adhesions brought about by the effects of the gas on the pleura." Are these desirable conditions?

Julian[19] writes me saying, "At present I cannot commend the method as fully as I would like." Homan[19] writes saying, "I have never been very enthusiastic about the operation." Thompson[19] writes me that "he feels sure the pendulum will slowly swing back to a more conservative basis in the use of artificial pneumothorax." Pierce[19] writes me that "it is not to be used indiscriminately."

Sajous,[20] in writing of the treatment of pulmonary hemorrhage, states: "In hospital and sanatorium practice, also in large cities, we have a much more certain and safe remedy in compression of the lung by gas injected directly into the pleural cavity." He also writes, "In profuse hemorrhages, where the pressure need be only temporary, oxygen gas, as found in the markets will be all that is required, as ere it is absorbed a clot will be formed." James,[21] in writing of compression in the treatment of tuberculosis, in conclusion states, "This method was practised for several years, but has now been generally abandoned."

So far as artificial pneumothorax in the treatment of tuberculosis is concerned, I admit I may seem to be rather pessimistic. I shall want a more uniform report of the results obtained, and better reasons for their having been obtained than have yet been furnished. I do believe, however, that the operation is clearly indicated in cases of uncontrollable hemorrhage, where all other means have been exhausted and the life of the patient seems in imminent danger. Here the compression need not be kept up long enough to bring about many of its dangers. Here it is an emergency measure, and seems rational and justifiable. This is in keeping with the opinion of Sajous, whom I do not find advocating the operation for any other purpose.

Many compressionists say that the operation is dangerous, requiring great skill and knowledge. I agree with them that it is dangerous; not, however, because of the necessity of an almost superhuman skill, but because of the direful results in such a large percentage of cases. Even by those to whom the greatest skill is attributed, many disappointments are admitted.

We are warned against overenthusiasm by many compressionists. Is it because they have found it not to be the wonderful life-saver after all? Is it because they have had so many accidents they are wanting to see the pendulum swing back in the other direction? Is it because they believe the consumptive already has enough trouble without adding compression to his depression? It may be better to pay more attention to the cause of the disease, the tubercle bacillus and its usually associated mixed infection, and a little less attention to the symptom complex, except in so far as it may aid us in making an early diagnosis and directing us in our fight against the cause.

A more or less extensive experience with the tuberculous, covering a period of about thirteen years, has brought my mind to the point where it dictates that early diagnosis, hygienic, dietetic, and medicinal treatment, and careful general management of the case, afford the safest and surest means of cure of pulmonary tuberculosis. I present this paper with the hope that it may assist in turning the pendulum on its backward swing, and that it might deter from the indiscriminate practice of compression that is being followed by some to-day.

THE CARE OF THE FEET IN PREGNANCY.

By GEORGE GELLHORN, M.D., F.A. C.S.,

ST. LOUIS, MO.

ASSOCIATE IN GYNECOLOGY, WASHINGTON UNIVERSITY MEDICAL SCHOOL.

A FEW months ago, Grossman (MEDICAL RECORD, 1916, XC, 1074) called attention to a hitherto neglected subject, the care of the feet in pregnancy. In this article the author, who has studied the question from the standpoint of the orthopedist, arrives at the conclusion that all pregnant women should be instructed as to the proper care of the feet; that prophylactic measures should be instituted regardless of the presence or absence of weak feet; that neuralgic pains in limbs, back, and sciatic region are suggestive of weak feet; and that only by the institution of prophylactic and of early active treatment can we hope to prevent severe suffering in one of the most trying periods in a woman's life.

Strange to say, obstetric literature contains no allusion whatsoever to this subject, and yet it is an every-day experience of obstetricians to hear patients complain of weakness of their feet during the first weeks or months after childbirth. This weakness may persist in some instances, and may become a permanent drag on the efficiency of the body. It is a well-known fact, both to physicians and the laity, that after parturition the feet often increase in size and that larger shoes are needed. This may seem trivial to the medical attendant, but it is a very real drawback to the young society matron, and, indeed, to any woman who wishes to preserve her physical attractiveness.

Moreover, such an enlargement is more than a mere cosmetic blemish, as it were. It represents a true pathological alteration with a clear-cut etiology. Let us bear in mind that in pregnancy all tissues of the body are more succulent. The joints share in the general succulence and thus become softened and looser as pregnancy progresses. This physiological fact is so well known as far as the pelvic joints are concerned that we take it into account in slight degrees of pelvic contraction; hence the usefulness of the Walcher position. The foot joints are subject to the same changes; but what originally was physiological and transitory may eventually become pathological and permanent if the increased weight of the body is permitted to rest upon the foot which is not properly supported. Many pregnant women avoid active exercise, particularly walking, and in consequence the muscles of the foot and leg, which should share the burden, become weakened so that the ligamentous structures largely have to bear the strain.

During the puerperium the muscular weakness makes rapid progress, and the flabbiness of the calves testifies to the extent of atrophy through inactivity. The coldness of the extremities, the tingling sensation in the feet, and the weakness of the knees on the first attempts to rise from the lying-in bed, may be the forerunners of a permanent flat foot, with its various unpleasant consequences. That not every woman retains this weakness illustrates the marvelous recuperative power of the human organism, but as we can not foresee the ultimate outcome, it behooves us, as obstetricians, to forestall any possible invalidization of our patients.

The prevention of weakness of the feet is so simple that one might wish the obstetric textbooks would, in future, devote a small space to its consideration. The obstetrician may begin his prophylactic attention long before the orthopedist has the opportunity. The patient who complains of painful feet in pregnancy should not be consoled with the thought that this "inevitable discomfort" will cease with the birth of the child, but the foot should be strapped at once and the strapping continued as long as necessary. A suitable shoe should be prescribed by an orthopedist. At the same time, *methodical* exercises tending to strengthen the plantar muscles, the tibialis posticus and anticus, and the group of muscles that give spring to the foot, should be instituted. The patient is seated with the knees crossed. The foot (not the leg) is slowly bent upward and downward; then follows a complete rotation in the ankle joint to the right and another to the left. These exercises are gradually increased in number until each is taken fifty or more times. To still further strengthen the plantar structures the toes are trained to grasp a small solid rubber ball about the size of a "ping pong" ball, and this exercise, too, is gradually increased.

It is not enough to merely suggest exercises; one has to insist on their proper and *regular* performance. I admit that it is not always easy to overcome the indifference of the patient and to strengthen her will power, but earnestness on the part of the physician, and, in many instances, the dread of a shoe of larger size, will accomplish the desired result.

During the puerperium, regularity and gradual increase of these exercises is facilitated by the help of the nurse. Moreover, most patients are only too glad to vary the monotony of the lying-in state. The exercises may be commenced on the day following delivery and need not be delayed more than a day or two even where lacerations have been repaired.

I have carried out the plan, as outlined above, for a number of years, and I can attest how gratifying it is to both patient and physician to observe the ease in taking the first steps and the influence this apparently insignificant detail has had upon the general wellbeing. It may be added, parenthetically, that the same exercises are most useful after any gynecological operation and help to shorten the convalescence.

The tendency toward flat foot is but one of the many untoward sequels which pregnancy and parturition may produce in the female organism. A very large percentage of gynecological patients date their ailments back to some previous labor or miscarriage. Many of these affections are preventable. It has always seemed unfair to me that women should have to pay a penalty for motherhood in the form of more or less serious infirmities, and I have for many years endeavored to eliminate, as far as possible, the *avoidable* after effects of gestation. I have elsewhere[1] described the appropriate prophylactic and therapeutic measures which will restore the muscular strength of the abdominal wall and the pelvic floor, and Grossman's plea for a better care of the feet in pregnancy now gives me an opportunity to record my own observations, which so closely coincide with his.

The object of the modern obstetrician is not merely the delivery of a living child. A higher valuation of his responsibilities demands of him that the mother, as well, should be restored to perfect health; and this purpose can best be obtained if a prophylactic regime be carried out which considers every part of the maternal organism and prevents, as far as lies in our power, any harm that may come from pregnancy and parturition.

METROPOLITAN BUILDING.

A CASE OF BOTHRIOCEPHALUS INFECTION.*

BY C. G. McGAFFIN, M.D.,

KINGS PARK, N. Y.

BOTHRIOCEPHALUS LATUS is a rare parasite in the United States, as evidenced by the small number of cases in American literature. However, it is thought that there are cases where the presence of the worm has not been discovered, so that perhaps it is not so uncommon as has been supposed. It is interesting to note that several observers, who have had their attention called to the parasite by finding it once, have discovered it in other cases. It should at least be borne in mind when treating foreign born patients, especially Finns and Swedes.

Schauman, in Germany, reported cases in which the worm was harbored from childhood to old age, and cases have been reported in this country where the parasite had apparently existed many years.

It will not be necessary to describe the parasite here, except to point out that it is the largest of those found in humans, and that the separate segments have the sexual pore opening in the median line in distinction from the Tænia, in which it opens on the side. French Switzerland and the Baltic provinces of Russia are the centers of distribution.

Bothriocephalus is acquired by ingesting its plerocercoids with various fresh water fish, in whose internal organs and musculature they live. The fish are not well cooked, or certain portions are eaten raw, and the cycle is thus started in a new host. The development of this so-called "broad tapeworm" is rapid, Braun stating that in some experiments he made the average number of proglottides formed per day averaged 31 to 32 for five weeks, with a length of 8 to 9 cm. The symptoms of the parasite's presence in the alimentary tract are not constant in their character. In many cases they are trifling and again, in others, they are intensely severe. There may be gastric disorders and nervous symptoms, with melancholia; in a number of cases there is severe anemia. Anemia is not a common symptom, however, and is apparently not influenced by the number of parasites, or the duration of the infection. R. L. Wilson reported a case of multiple infection in which there were thirteen worms with an aggregate length of 319 feet; the known duration was over five years, but there was no noticeable anemia. On the other hand, one of Edsall's cases gave a red cell count of 662,000 at one time with a known duration of infection of only six weeks, while the count in the case I am reporting was 651,000 with unknown duration of infection. So the finding of the eggs in the feces is the real diagnostic sign.

The case which forms the basis of this paper is offered, not so much as a curiosity, but for the fact that the presence of the worm was masked by physical symptoms which apparently had no relation to it. Unfortunately death resulted and the parasite was found post mortem—the correct diagnosis having been made, however, a few days previous.

E. F., female, aged 30, admitted to Long Island State Hospital February 18, 1910. Born in Finland; father dead, mother alive and in Finland; two sisters and one brother—one sister is married in California, the other sister had been a patient at Kings Park. Patient came to the United States in December, 1906, and had worked as a domestic servant; when working out seemed to find it hard to get along with people; was cranky and irritable and could not keep a position. Could read and write.

For a year past she had acted and talked queerly; thought people were talking about her and that they had a machine that could know everything concerning her; also heard voices talking to her in her native tongue.

On admission, skin and mucous membranes good color; hemoglobin 85 per cent.; physical examination negative.

Mental Examination: Was quiet and orderly; partially oriented; hallucinations of hearing which could not be described but were annoying—plugged her ears with cotton in endeavoring to stop them. Following admission remained quiet and orderly; hallucinations

[1] The Physical Culture of the Puerperium, *Interstate Medical Journal*, Vol. XVI, 1909, p. 1. The Management of the Puerperium—A Chapter in Preventive Medicine, *Lancet-Clinic*, 1909, Vol. CXI, p. 722.

*A contribution to the William Leonard Worcester Memorial Series of Danvers State Hospital Papers, presented November 19, 1915.

active, and states that she is influenced by a machine affecting various parts of her body. "Sometimes I get very hot in the head; they boil my head." "Make me sick to my stomach." "That is a terrible machine." Continued without change and was transferred to Kings Park State Hospital on May 8, 1911.

In August, 1911, complained of headache and dizziness, and was in bed about ten days; temperature 100.6° to 102.5°. August 17, chest was examined and found negative. August 23, was up and dressed and appeared normal. Mentally no change.

In February, 1912, said, "I am feeling no good—sick all the time—nervous—like tired; can do nothing." Complained very often of headache. In April, complained of headache, and note states, "she looks pale"; some cough, but no expectoration; Von Pirquet test positive. Evening temperature 102°. Some dullness over left apex with a few fine rales. Reported as a case of tuberculosis. September, 1912, vomited and complained of feeling weak. Temperature 104.8°. Blood examination for malaria and Widal negative. Examination of heart showed "mitral insufficiency and endocarditis." Splenic dullness increased; diarrhea. Was treated as a case of typhoid. Made a good recovery from this condition and was up in eight weeks. Gained in weight from 110 lb. in June, 1912, to 136 lb. in March, 1913. Coughs, but there is no expectoration. In June, 1913, said to show good healthy color; physical examination shows infiltration of left upper lobe. Mentally unchanged. In September, 1913, "does not cough or expectorate." There was a gradual loss of weight beginning July, 1914. Temperature ranged from 98.4° to 100.2°. In December, 1914, appeared weaker and spent a few days in bed, but was soon up and in her usual condition.

January 9, 1915, was noted as again showing marked weakness; complains of general malaise with frontal headache, and shows considerable anemia. Vomiting became an annoying symptom. Frequent loose cough, but the anemia and cough seemed out of proportion to the findings in the lungs. January 23, 1915, red cells 651,000—blood smear shows macrocytes, poikilocytes, an occasional myelocyte and nucleated red cell; white cells are diminished in number. Diagnosis of infestation by *Bothriocephalus latus* made. Patient seemed too weak for vermifuge; failure was rapid and death occurred on January 25, 1915.

Necropsy was performed 64 hours post mortem. Body is that of a well developed, fairly well nourished young white female; height 159 cm. Weight 97 lb. No bruises or abrasions; pupils regular in outline—equal—3 mm. in diameter.

Ventral Section: Abdomen is flat; panniculus 1 cm. in thickness; abdominal muscles thin and pale; some fat in greater omentum, which is well developed and covers the contents of the cavity completely; the intestines appear very pale, almost transparent, and are distended with gas; appendix is normal in position and appearance, 5 cm. in length; diaphragm normal; no adhesions or exudate in abdominal cavity.

Thorax is small, but well developed; mammæ pendulous; pectoral muscles thin and pale; costal cartilages show no change. The lungs, with the heart, completely fill the cavity; there are slight adhesions on both sides, but they are easily broken up; no fluid in the pleural cavity.

Pericardium is normal. Heart weighs 380 gms. There is some fat on the surface; the cavities contain a small amount of fluid blood which appears very pale and watery, with no clots; myocardium is pale and flabby; mitral valve shows some thickening along the edges; other valves negative. There is no thickening of the vessel walls and no varicosities. The lymphatic system shows no hyperplasia, or other abnormalities.

Trachea and bronchi show nothing of note Pleura thickened at apices. Right lung weighs 494 gms. The tissue is of about normal appearance; no tubercles are noted in the gross; there is some edema and congestion, but substance crepitates throughout. Left lung weighs 435 gms. It is similar in all respects to the right.

Esophagus normal. The stomach contains a small amount of light colored fluid material; mucous membrane pale; no hemorrhagic areas. Intestines are somewhat distended; walls very pale. On opening the small gut it is found to contain a large *Bothriocephalus latus* measuring 24 feet in length. Microscopic examination of the fluid contents of this portion of the intestine shows many of the ova of this parasite. Large intestine negative. Liver weighs 1,495 gms. Surface is smooth and on section the tissue is pale and appears waxy in consistency. Gall-bladder contains a small amount of normal looking bile; no stones. Pancreas weighs 130 gms.; is large and soft.

Kidneys, weight 320 gms. They are large, soft and light in color. The capsule strip easily; cortex and pyramids are well made out. No fat in the pelvis. Ureters and urinary bladder normal. Uterus and appendages normal.

Spleen weighs 120 gms. The capsule is not thickened and on section the pulp is pale and soft; no increase in trabeculæ. Adrenals weight 25 gms. and appear normal. Thyroid not examined. Pituitary normal.

The scalp is covered with a good growth of light hair; it is not thickened and strips readily from the bone. Calvarium is normal in shape and character. Cranial capacity is 1303 cc. Dura mater weighs 50 gms.—normal. Piaarachnoid is thin and pale, and shows no exudate. Brain weighs 1245 gms. before dissection and 1235 gms. after dissection. Cerebrospinal fluid is not in excess. Vessels show no sclerosis—substance markedly anemic. Cerebrum shows no atrophy, the gyri being well filled out and the surface pattern is regular; ventricles are smooth, and on section there is nothing noteworthy. Cerebellum, pons, and medulla normal in the gross. Spinal cord not removed; upper section normal.

Microscopically, the heart showed slight fatty infiltration. The lungs showed thickened pleura, some infiltration of leucocytic exudate, and much edema. No evidence of tubercles. Liver presented a thickened capsule—much fatty infiltration with some degenerative changes. Spleen, capsule thickened; much increase in the red cell content of the pulp. Pancreas, great amount of fat replacement, with some areas of degeneration. Kidney, capsule thickened; much cloudy swelling of tubular cells. Cerebral cortex, Betz cells showed acute cell changes and there was some degree of satellitosis—deposit of yellow pigment in cell bodies. Cerebellum, nuclei of Purkinje cells are not well made out; otherwise negative. Cord, ependyma of central canal much proliferated; polar cells of anterior horns show loss of granules and nuclei are faint.

The case presents several interesting points. The duration of the life of the parasite is uncertain, but surely it must have existed prior to the patient coming to the United States, or over eight years at the time of her death. Might not the acute attack in the fall of 1912, which was treated as typhoid, have been a toxemia caused by the parasite?

The presence of anemia of such an astounding degree in some cases, and none in others, is a very puzzling condition and one for which no adequate solution has been offered. In this particular case the physical signs in the lungs, together with the temperature, masked the condition in the intestines and in fact that was no symptom of the bothriocephalic infection until the anemia became such a prominent characteristic. There was no diarrhea to point to intestinal disturbance, and no segments of the worm were found in the stools. It is an unfortunate characteristic of the broad tapeworm that it does not give up portions of its anatomy by which it may be identified. No examination was made for the ova.

It is important to remember that in individuals from the Baltic countries, especially, the Bothriocephalus is a frequent parasite and in some cases, perhaps, an examination of the feces for the ova of the worm will clear up a puzzling case. Again, the worm may exist for years and give no apparent symptoms, and then suddenly begin to develop in

its host a severe toxemia. Finally, the patient need not necessarily be a recent arrival in this country to present symptoms of Bothriocephalus infection.

MASSAGE AND EXERCISES IN THE AFTER-CARE OF POLIOMYELITIS.

By FRANCISKA BERG,

NEW YORK.

THE treatment of poliomyelitis and the ultimate restoration of function, after the disease has passed the acute stage, depend in large measure upon the special skill and judgment with which exercises and massage movements are administered to the paralyzed parts. The cases presented here are cited to illustrate what it is possible to accomplish by means of scientific massage and body movements administered in co-operation with the medical care of the patient.

CASE I.—A little girl, eighteen months old, living in a town suburban to New York, whose distress had been witnessed by physicians of the metropolis and the community where she lived, was regarded as the most serious case of infantile paralysis that had come under their observation. She had been stricken with the disease at the age of eight months, and was in a pitiful condition when in the summer of 1914 I began my treatment, she being so delicate that it was extremely difficult to handle her. She was lying on her back in braces which covered her body completely from the feet up to the shoulders; the arms and hands were also imprisoned. She was lying in these armor-like enclosures twenty-three hours of the day, and could do little more than move one arm. Her back was as weak as that of a new-born child. The abdominal muscles were also weak. The neck muscles were contracted, so that the shoulders were drawn up to the ears, making the chest narrow and sunken. The lavator scapulæ was paralyzed on the right side, and both deltoid muscles were paralyzed. The arms were partially deprived of function. She could move the right forearm slightly. The shoulder and arm muscles were atrophied. The left arm had so great a pronation contraction that the palm of the hand was turned upward. The right hand had a palmar contraction. Both legs and feet were paralyzed; the legs were rotated outward. The gluteus maximus on the right side was atrophied, giving this part of the body a concave rather than a convex outline. The left knee had a flexion contraction, the left foot so great a supination contraction that the sole was directed upward. The right foot had a great plantar contraction, so that it looked like a clenched fist, and there was a marked contraction of the tendo Achilles.

I treated her for about three months, six days a week, during my summer stay at her home. After my return to New York I had occasion to treat her only two or three times a week for a little while, then leaving her to the care of her mother, whom I had taught a few exercises and light massage movements for the case.

When I left this little patient her back was sufficiently strong to enable her to sit up by her own strength; she could bend her head down to her feet and raise it again, turn over, and move both her forearms and hands, and play with her toys. The contraction of the neck had disappeared and the chest was nicely developed. All the other contractions were greatly bettered, as was also the condition of the abdominal muscles. She could move her legs and feet a little and keep her legs together when placed in the right position. The atrophied gluteus muscle had developed to normal size, and the arm and shoulder muscles had improved a great deal. The general condition of health was excellent.

The parents will now arrange to have the child stay for a longer time in New York and continue the treatment. I have already worked with her one month. When lying on her back with flexed knees and resting on her neck and the soles of her feet, she can now easily raise her body to the highest degree possible in that position. Her feet are so well developed that it is possible for her to maintain the above-mentioned position, lying on her back. She can rotate the legs inward and outward, abduct and adduct them a little, can raise her arms above her head and lower them again, can lift her right arm in its whole length and swing it over to the left side. She can move her left forearm in all directions. The contraction in the left arm has not yet been conquered, but she can without aid pose her hand and keep it in the right position. The other hand is normal. The contraction of the knee is much improved. When lying on her abdomen she can raise her back as high as it is normally possible when resting on the forearms; she can bend and stretch the right knee; the left leg is weaker, but it is probable that in a short time she will be able to do the same movement with that member.

Infantile paralysis leaves its victims more or less crippled and the inactivity of the patient, caused by the paralyzed parts of the body, hampers improvement. Therefore, the first essential is to work up the general circulation by means of breathing exercises, so that the lungs may be filled with fresh air and the stationary air be expelled. This is done by drawing the arms of the patient upward when lying on the back, and moving them slowly downward again under as much voluntary inhalation and exhalation as the patient is able to command. This exercise expands the chest, stretches the spine, and works beneficially upon the muscles of the abdomen. Thereafter, spinal treatment should be given before administering local treatment. One must, in an artificial manner, try to produce the same effect for the patient as a healthy person gets from his daily movements.

The exercises, as well as all the massage movements, must be very carefully done and always specifically with the needs and condition of the patient in view, for otherwise harm rather than good may be done. One must bear in mind this purpose—to build up affected limbs and to improve the general health. A rule in the science of mechanotherapeutics is that it is better to do too little than to do too much. It is, of course, understood that the massage exercises must be highly developed and scientifically applied, in order to be able to restore the function which infantile paralysis has destroyed in its victims. The hand and wrist of the practitioner of massage must be trained somewhat like those of a pianist for acquiring the soft, gentle, and yet strong grasp which is a necessity for obtaining good results.

Scientific massage can give results in infantile paralysis cases that are equalled by no other treatment. It improves the nervous system and the circulation of the blood, principal factors for improving paralyzed limbs, atrophied muscles, and weak joints. Together with the technique of massage go the exercises designed for each particular case, first passive ones that are replaced later by active, free or resisted, exercises when the patient is able to perform them—in concentric and eccentric form, as the muscles may be affected, contracted or elongated.

CASE II.—A patient I had in 1915, a boy nine years old, was stricken with infantile paralysis at the age of two. His right leg and foot were affected. The power of movement was absent and the leg muscles were greatly atrophied, as was also the gluteus maximus. The hip and knee joints were weak. An operation had been performed a few years previously for the purpose of keeping up the dropping foot, and through

this the ankle had become stiff. The child limped badly, mainly because he carried the whole weight of the body upon the strong leg, which caused the knee to bend in walking. He dragged the paralyzed foot after him. The unaffected side had been over-developed through too much use. As he was the only child of well-to-do parents, many things had been tried for seven years in order to restore movement in his affected leg and foot.

After four months' treatment the atrophied gluteus muscle was developed to normal size and the joints were strengthened. The calf muscles developed slowly, but there was considerable improvement. He could walk quite normally with the help of a cane, and go up and down stairs. He could also run, go about on roller skates, and drive a saw machine with the affected foot, the ankle of which had been worked up so that he could move it a little. The toes were very flexible.

Case III.—A young girl, seventeen years of age, had suffered from the effects of infantile paralysis for four years, during which time she had had the best possible care. When I began to treat her the back was so weak that she could not raise herself from a lying position nor sit up without help. Her shoulder joints were weak, also her right arm, which had a thenar atrophied hand. Both legs and feet were affected. The different muscle groups of the legs were pseudohypertrophied, so that these limbs were quite stout, heavy, and shapeless. There was no movement possible in the legs and the feet. Owing to deficient circulation, the lower parts of the legs and the feet were cold and of a dark violet color. She was supported by braces going from the feet up to her waist, and by stays made of steel bands. In a sort of gymnasium that had been especially prepared for her, two bars were erected. When placed between them and resting the hands on the rails, she raised one side of the body and forced the leg forward a step, when resting on the other. In that manner she had tried to learn to walk.

I have treated her three times a week for about four months. She can now sit up of her own strength, which achievement she and her parents have regarded as the great event in her long illness. The different muscle groups of the legs have been freed from superfluous tissue, and the circulation has improved. There is a beginning of rotation in the legs, and when lying face down she can flex and extend the left knee; she will soon do the same with the right one. She can now move her toes, and the shoulders are stronger. She is beginning to walk with unlocked knee joint of the braces.

Case IV.—The following case is not one of poliomyelitis, but it may be of interest in this connection. A boy of six years, the child of well-to-do parents, had been under the best possible care during his long illness. He was a large and strong child at birth, but was overfed by a nurse, and when he was three weeks old he became so ill that his life was despaired of. He lived, but for the following two years it was very difficult to feed him. In consequence, he was far below normal in size and strength. At the age of two he was attacked by dysentery. He survived, but for the next four years a fight had to be made for every ounce the child could gain. He was so weak and emaciated that it was necessary to keep him flat on his back most of the time. When about five and a half years old, his digestion had become almost normal, but the long inactivity had resulted in atrophy of the muscles. He was no taller than a child of three years when I began to treat him. He was then six years old, and could remain on his feet only for a few minutes when resting his arms on his little table. His ankles were so weak that the feet dropped. The abdomen was of an enormous size. He was retarded in speech and could say only ten or twelve words.

The first thing to do was to try and work up the circulation, and through tapotement on the back to reach the various abdominal organs. This vibratory massage movement had so beneficial an effect that it was possible after a few weeks to give light massage of the abdomen itself. After four months' treatment the patient could walk, get in and out of the bed by himself, climb a ladder, and taking hold with both hands of one of the rungs of the ladder, swing his body freely. His muscles developed well, his general state of health became excellent, and he could talk normally as a boy of his age. His abdomen diminished and became normal in size. A year afterwards I heard that he was gaining so rapidly that the probabilities are that by the time he is ten years old he will be normal in size and strength.

Hotel St. Andrew,
Broadway and Seventy-second Street.

Medicolegal Notes.

Medical and Surgical Service Under Workmen's Compensation Act.—Indiana Workmen's Compensation Act, Section 25, provides for the furnishing by the employer to an injured employee of an attending physician for thirty days after the injury, and thereafter at the employer's option, "Provided, however, unless otherwise ordered by the Industrial Board," and in addition such surgical and hospital service and supplies as may be deemed necessary by said attending physician or the Industrial Board. This proviso is held to be a limitation or qualification of what precedes and not on what follows; and whatever authority is given as to determining the necessity for surgical and hospital services and supplies is lodged in the board and the attending physician. The final determination rests with the board. There is no authority to furnish the surgical and hospital service except during the thirty-day period, and so long thereafter as the employer furnishes a physician. If an emergency arises for either of the services provided for at a time when it is required to be rendered, the employer by mere delay in rendering the service cannot escape liability for any which should and could have been rendered within the period during which it is made his duty to perform it. So, if the board is of opinion that the evidence before it shows the emergency for amputation of an employee's foot arose before the expiration of the thirty days, and that the amputation should and could have been performed before the expiration thereof, and that the employer was responsible for the delay preventing it before such expiration, the board can hold the employer liable for any surgical and hospital service and supplies that might have been furnished within such period, though not furnished till thereafter, the board's determination of which question of fact is conclusive.—Henderson, Indiana Appellate Court, 116 N. E. 315.

The wisdom and fairness of such a provision as the above are justified in other jurisdictions upon the ground that the employer is interested in a speedy and complete recovery of the injured employee in order that it may be relieved from payment of compensation at the earliest moment possible.—Keigher v. General Electric Co., 173 N. Y. App. Div. 207, 158 N. Y. Supp. 939.

Rules for Mutual Benefit Societies.—A member of a mutual benefit society which has authority to amend its constitution and by-laws and change its rates, who has contracted that his contract shall be controlled by all laws then in force or that might thereafter be enacted, is held not entitled to complain of an amendment raising his rate of assessment in the Mississippi case of Neuman v. Supreme Lodge, K. P. L.R.A. 1916C, 1051.

The change by a man, without the knowledge or consent of his wife, of the beneficiary in a mutual benefit certificate upon his life, is held a breach of his antenuptial contract to take out the certificate in her favor, in Ryan v. Boston Letter Carriers' Mut. Ben. Asso., L.R.A. 1916C, 1130.

An Illegal Abortion is an Assault.—According to common law the producing of a criminal abortion resulting in the death of the mother is murder, but an Oregon statute has mitigated this to manslaughter, regarding the death as an involuntary killing of misdirected violence. In affirming a conviction of manslaughter under this statute, the Supreme Court says that the procuring of a criminal abortion involves an assault even when the woman gives consent, since no one can consent to an unlawful act; furthermore the woman cannot consent to the murder of her unborn child. The abortionist has the intention to kill the child and if, in attempting to do so, he also kills the mother, the death is not the result of accident but is the direct consequence of an assault.

Military Medicine.

LETTERS OF AN M. M. R. C.

THE daily routine in the Medical Officers' Training Camp is in no wise different from that of the ordinary recruits. Excuses, excepting those most valid, are of little avail. At five o'clock every morning there is a general stirring among the fifty cots in barrack. The lavatory, situated in a separate shack, though rough in appearance, like all the barracks, is thoroughly up to date in its appointments. There are eight shower baths, on a concrete floor, with hot and cold water attachments. This is the one and only luxury of camp life. At 5.30 A. M. the bugle sounds, and every one must be properly dressed, with hat on, in line. All the various companies of the medical division line up on the company street, between barracks, and face the physical instructor—an army officer—who stands on a raised platform in front. Now begin what is known in the army as "setting-up exercises." They are calisthenics (more or less difficult) in rhythm, by command. In the case of a man who has not kept himself physically fit the twenty-five minutes of setting-up exercises are apt to leave him pretty well blown and in a profuse perspiration. This reminds one of a fact worth here recording, *i.e.* that your kidneys are of absolutely no use from the moment you enter a training camp. You might just as well have them hanging up at home. At the completion of setting-up exercises you are marched into your mess hall for breakfast. This is 6 A. M. This meal consists of coffee, a cereal, and on your tin plate something greasy will appear, reflecting to a certain extent the feelings of your cook. Some seem to get away with this dish by pouring a plenteous supply of molasses over it. Others, more refined in taste, make up on bread and butter. As an incidental expense to camp life, it might here be stated that one of your own regiment is appointed mess sergeant. He does all the purchasing of supplies and paying of help. Each man in the regiment pays a dollar a day to the mess sergeant for his board. If there is anything left over at the end of the month a rebate is made. Between your breakfast, at 6 A. M. and 7, your time is your own after you have dusted and swept out the quarters alongside your cot and trunk. The sweepings all go in small piles in the center aisle, and are collected later on by the barrack orderly of the day (an appointment that each officer must fill during his time of training). Among the various duties of the barrack orderly, besides keeping the place clean all day long, he must keep the ice-water cooler supplied. This is no light task, for after every drill or march the thirsty and sweaty men hover like bees around it. To keep this water tank fresh and clean it must be scalded every day by the orderly. This he does at the kitchen. All sweepings, papers, and trash are thrown into a big box in front of the barrack by the orderly. This is emptied once a day by a wagon and crew for this purpose. Being in barracks all day long, the orderly is the one to take all messages that may come for any one belonging to that barrack. Although every one must perform this duty of barrack orderly once during his stay, it is also used as a punishment. If a man is constantly late in falling in line when orders come, the captain in command of this barrack can order him to orderly duty whenever he wishes. This can be made uncomfortable if he is ordered for such detail on Saturday, for this is the only day in the entire week, except Sunday, when one is allowed a half day off. Most men have something in particular they want to do, perhaps to get into the neighboring town, and this is the only chance they have of doing it.

At 7 o'clock the men assemble in line and the roll is called and special announcements are made and detail duty given out. The men march out on their morning hike four by four. The walk is out one of the country roads, in route step, at a good lively pace. Talking and singing are allowed. The distance they go on this hike depends on the time the first lecture will be called. If there is nothing till 9 A. M., they may be walked six miles, with a rest at distal ends. If the first lecture is at 8 o'clock it will only be two or three miles at a very rapid clip. The end of the morning hike will find every one again in a profuse perspiration. The time between this morning hike and noon is taken up by lectures out of doors, on the Army Manual and Regulations, drilling, map making, gunshot wounds and surgery in war time, sanitation, or some other such subject. This reminds me that each man, on arrival, is presented with six textbooks which cover the subjects on which his lectures will treat. These books do not have to be purchased by the man, but he has to sign a receipt for them and keep them in his possession. They are absolutely essential in making out reports to the Surgeon General and War Department. In time of peace, the Surgeon General and his aides, realizing that the average doctor at a military post had little serious to do, decided that they would make him earn his salt. To this end they devised the present system of procedure, which is as complicated as the maze of Hampton Court. If the slightest detail was not properly complied with the monthly report of the Post Doctor was returned to him for correction or information, and from then on the never-ending correspondence school between that surgeon and the office of the Surgeon General was started. Naturally, his superiors could employ more sarcasm in their letters to him than he to them. It is a safe prognostication that with the influx of Medical Reserves this entire paper system is going to break down, and it is the general opinion among officers that it will be little loss.

We have now come to noon and the midday mess. Once more the company falls promptly into line and marches into the dining hall. Any new announcements for the work of the afternoon are here made. As a rule it is "Be ready to fall in at one o'clock for drill." The drilling is the regulation army drilling of formation. Each company is an entirety, and the only time that all the different medical companies meet is in dress parade, usually held on the Parade Ground of the fort in honor of some visiting celebrity. Naturally, there is considerable rivalry for the oldest companies to outshine each other in military bearing and execution of maneuvers. It is really quite extraordinary what three weeks of intensive training can accomplish in changing the attitude of an individual who by

habit has done none of these things. Each company has its own individual commander, who is either a major or colonel in the Medical Department of the regular army. Acting under him will be a medical officer of the militia who has seen field training. He may outrank the one in command. The captain of your barrack is usually chosen from the same source. The commander of your company is the one who gives the lectures on Military Regulations and drilling. Naturally, there is rivalry on his part that this, his particular company, shall outshine all the others. It is a feather in his cap for any compliment given by the commandant of the post for his particular "lot of boys." Above all these commanders of the Medical Reserve Corps there is one commander to whom the others are responsible.

Instead of regular drilling between one and three o'clock, it may be "litter drilling," in order to perfect an officer handling an ambulance company, which consists of about forty men. Needless to say, this is a most important drill. In it one is taught how to take up and carry a man who is unconscious or wounded. This is not any easy task, and is well nigh impossible to perform if one has not been shown how.

Between three and five there are more lectures, or else parades. Between five and six o'clock the men can do what they wish. It is the usual time for taking to the shower bath and putting on clean things. At six occurs the evening mess, for which you have to fall in line promptly. You may have from now on till taps to yourself, or you may be told to meet Major So-and-So in the company street for an illustrated lecture on such and such. Taps sounds sharply at ten, and as the sound dies away you must be in bed, with all lights in barrack out. This ends the average day in military training camps. Every day in the week is about the same, rain or shine. The only real day of rest is Sunday, and this is rest in its fullest sense.

There is no doubt but that homesickness unrecognized plays a large part in the first week of the enlisted doctor's life in the Medical Training Camp. Nostalgic symptoms are evidenced by self-communion as to the advisability of having allowed his patriotic instincts to bring him to this pass. He recognizes the inviolability of the oath he has given the Government and the futility of his trying to change the situation. This nostalgia is as pronounced in the officers of advanced age, particularly if they are men of family, as in the younger generation. Some never having been accustomed to any discipline, refer their nostalgic blue feelings to restraint as a cause.

Among 99 per cent of the Medical Officers' Reserve Corps this nostalgia has entirely vanished at the end of their first week in camp, and they throw themselves heart and soul into the work before them. With every additional day the esprit de corps mounts degree by degree. Enthusiasm is seen everywhere, and there is no longer a single remaining regret for the step they have taken. This statement is not an exaggeration, and should help persuade the doctor who still hesitates to take the step that his patriotism dictates. If he saw, as we do every day, the boyish faces of the thousands who are throwing in their all for the cause of their country, if he realized as we do how dependent each one of these kids is on our profession to keep him straight and get him back to his mother and father and those that love him as good as he went, if not better—because you, as commanding officer of any ambulance corps, will have a chance of making them better men both morally and physically—if you could see this as we do you would feel yourself inhuman in delaying the answer to this call. You will find many men in these ranks of ours who have given up much more in all ways than you can possibly have to give. There is no feeling of sacrifice, but a great and unending joy, to feel and know that you did as the spirit prompted. It is a heritage that nothing can buy.

The Casualty Clearing Stations.—From the viewpoint of Anthony Bowlby and Cuthbert Wallace the development of the casualty clearing stations has been the most important factor in the creation of a new school of surgery at the front; they have saved many thousands of lives which would have been lost but for the surgical opportunities which they have provided. Before the war the "C.C.S.'s," as these stations are called, appeared only on paper and as untried units, for they did not exist at the time of the South African war. Their equipment was slight and their staff of eight officers, including the command officer and the quartermaster, was less than the staff of a field ambulance. They carried 200 stretchers and were supposed to be able to deal with the same number of patients. The six casualty clearing stations which came with the original Expeditionary Force were decidedly overtaxed; it became evident during the first battle of Ypres that these clearing stations might well be made the nucleus around which to build an efficient organization for much more complete surgical treatment than had been originally planned.

The first change which had to be made in this organization was an increase in the supply of bedsteads with bedding, and the appointment of trained nurses; the next was the addition of more surgical equipment. The selection of special surgeons naturally followed, and before the end of 1914 good surgical work was being done in eight centers, and by the end of 1916 more than fifty casualty stations were at work.

These hospitals, behind the lines along the entire front, must be at or near to railway sidings, so that evacuation by train is easy; they must also be where good roads can connect them with the front, and they must have a good water supply. They are practically arranged in two series, those at the front are at a distance of from six to nine miles from the front trenches, while those of the second line are from three to six miles further back, and act as a reserve during active operations, or as units for special cases during quieter times. The smallest stations accommodate 400 to 500, and the largest from 800 to 1200 patients. Wherever possible these stations are linked in pairs, and take in the wounded alternately. By this plan the wounded are diverted to other casualty stations, and the staff is left free to treat those they have taken in without being disturbed by fresh arrivals.—*British Medical Journal.*

Army Orthopedic Board.—Surgeon-General Gorgas has announced the formation of a new department of Military Orthopedics. This step has been taken because from 30 to 40 per cent. of the casualties of the present war require special orthopedic treatment, and also because from 70 to 75 per cent. of the cases can be restored to military usefulness. Major Elliott G. Brackett, R. M. C., has been appointed Director of Military Orthopedics, with the same headquarters as the Director for the Expeditionary Forces. So much special organization will be required that the office of Director of Military Orthopedics for the Expeditionary Forces has been created, and Major Joel E. Goldthwaite, M. R. C., has been appointed to fill that position. Associated with him will be Major Robert B. Osgood of U. S. Base Hospital No. 5, and Capt. Nathaniel Allison, now with Base Hospital No. 21, will be transferred to this department. Major Osgood will be assigned to report to Col. Robert Jones, Director of Military Orthopedics for the British Expeditionary Forces, for the study of the details of organization and the methods of treatment. Captain Allison will be assigned to similar duty with the French and Italian forces. An Advisory Orthopedic Board has been appointed for the assistance of the directors; it is made up of Dr. Robert W. Lovett of Boston, Dr. Albert H. Freiburg of Cincinnati, Dr. Gwilly Davis of Philadelphia, Dr. F. H. Albee of New York, and Dr. John L. Porter of Chicago.

Gift for Dental Ambulances.—The Preparedness League of American Dentists has received a gift of $10,000 from Mrs. William B. Thompson to equip five dental ambulances for the New York State troops. The ambulances will be tendered to the Government through the Red Cross Society. This is the first large donation that the league has received toward the equipment of the many dental ambulances which it expects to send with the expeditionary forces.

Cooperation Between American and French Red Cross.—A cablegram has been received at the headquarters of the American Red Cross announcing that General Pershing has appointed Major M. P. Grayson Murphy as one of his staff, and that arrangements have been further perfected for caring for American troops en route for the front. It is stated that on the way from the reception camp to the training ground, a journey that takes seventy-two hours, there are six infirmaries and rest stations, each in charge of a nurse, so that no soldier who falls ill on the way will lack attention.

Ethan Allen of New York has been appointed director of the Atlantic Division of the American Red Cross, which includes New York, Connecticut, and New Jersey, having a total of 214 chapters and 668,257 members. He will have entire charge of the Red Cross work in these States.

War and Crime.—A recent report to the New York *Sun* records the doubling of the number of criminal offences committed in the city of Amsterdam, Holland, since the beginning of the war. The police superintendent of that city attributes this in part to mental aberration resulting from the great conflict, and in part to the increased opportunities for smuggling and espionage, to increased poverty, and chronic idleness. Special mention is made of the fact that there is increased criminality among children.

Red Cross May Call More Nurses to Service.—At a conference recently held between the Red Cross Committee on Cooperation, the Red Cross Medical Advisory Board, and committees representing leading nursing associations of the country, estimates were presented showing that approximately 14,000 nurses may be called into war service within the next 18 months. This number should be able to care for an army of 2,000,000 in the field. More than 12,000 are already enrolled in the Red Cross, available for instant service.

Surgical Dressings for Red Cross.—From Washington comes the announcement that all Red Cross chapters in the United States were ordered on July 18 to send in their stock of surgical dressings to meet demands from the Allied front in Europe.

Social Hygiene for Soldiers.—The Surgeon General's Office has announced a program for combating the venereal peril, which has always presented a serious problem when troops have been assembled in the vicinity of a civil community, and which neither the military nor the civil authorities alone have been able to control effectively. The measures proposed provide for the cooperation of the Army Medical Department, the United States Public Health Service, the War Department Commission on Training Camp Activities, civil authorities, and non-official agencies. As the Army Medical Department is limited in its strictly official capacity to measures for the prevention and treatment of venereal disease inside the military encampments, a section has been organized to devote itself to this problem, with an officer in charge of laboratory investigations, one in charge of the medical work, and one in charge of educational and environmental measures and sociological studies. Although the creation of this section is new, the work which it is to do has been carried on for years by the Army. The Public Health Service has been charged with the responsibility for health conditions in civil sanitary districts surrounding military establishments. The work will be done in cooperation with State and local authorities and with the American Red Cross through an advisory board. The Commission on Training Camp Activities is to see that the laws with reference to the elimination of commercialized prostitution, the sale of alcohol and habit-forming drugs, and gambling are enforced, and to provide proper recreation for the soldiers. This part of the work the civil authorities and non-official agencies are to supplement.

Protest Against Drafting Medical Students and Hospital Interns.—At a meeting of the Mayor's Committee on Hospital and Medical Facilities, held at City Hall, New York, on August 15, 1917, the following resolutions were unanimously adopted, and signed by the representatives of over thirty hospitals in New York:

Resolved, That the Mayor's Committee on Hospital and Medical Facilities call the attention of the Secretary of War to the serious consequences to the civilian population of the country, and to the maintenance and operation of the hospitals, of the inclusion of medical students and hospital interns under the act of selective service.

Further Resolved, That the chairman be directed to lay the views of this committee before the proper officials of the Government, and the District Boards

of the State of New York, and to take the necessary steps to bring about the temporary exemption of those students and interns in order to secure a constant supply of medical men to the Army throughout the war and to prevent the embarrassment of hospitals and the consequent serious results to the population of the United States.

Canada's Army Hospitals.—In the military hospitals in Canada there are 8,811 soldiers receiving treatment, 320 new patients having very recently been added to the list of convalescents. The number now in convalescent homes is 7,032, with 1,104 in sanatoriums for the treatment of tuberculosis, and 675 in other institutions, chiefly general hospitals.

Specialists for Cantonments to Be Selected.—The sub-committee of oto-laryngology, working through the Council of National Defense, have sent a questionnaire which would furnish the special training and experience of the men addressed to 6,000 oto-laryngologists, and 2,500 replies have been received. These have been properly filed, and all the necessary blanks for entering the Medical Reserve Corps have been sent to the oto-laryngologists who have signified their willingness to enter this branch of the service. Through the office of the Surgeon General, boards of examining specialists are in the process of selection. The subject of revision of the standard of hearing required for acceptance in the Army has been discussed and recommendations made. Tests for detecting feigned deafness have been selected and submitted for approval. A plan for a special ward in each cantonment hospital for nose, throat, and ear examination has been drawn up, and will be submitted for approval.

Suggestions by the Surgeon General.—The following paragraphs have been added to a letter from the Surgeon General to the chairman of the State committees of the medical section, Council of National Defense: "(1) It is believed that it would be of great advantage to this department if each State committee would make a census of its State, with a view of dividing the medical profession into two classes: (a) those who cannot be spared for Army service because of their importance to the civil community, and (b) those who can be spared. Class (a) should be requested to refrain from offering their services. Class (b), on the contrary, should be encouraged promptly to apply for appointment. (2) The department will not feel called upon to consult the list prepared under paragraph 1 when individual applications are received, since it will be assumed in all cases that the individual offering himself can be spared, and will be at the disposal of the department for such duty as the exigencies of the service may demand. (3) For the purpose of this census the State committee should act as a clearing house for the county committees."

Surgical Dressings for American Naval Vessels.—The Red Cross, upon the request of the Surgeon General of the Navy, has called upon ten of the larger chapters nearest New York to supply at the earliest possible moment surgical dressings for battleships and destroyers. The required consignment of surgical dressings will make a total of more than 600,000. This order is to be filled within ten days. Each chapter will supply the battleship named after that particular State, and others in which they have a geographical interest. Thus the Chicago Chapter will supply the *Chicago* and the *Illinois;* the New York Chapter the *Albany* and the *New York,* etc.

American Ambulance Hospital in Paris.—Mrs. Robert Bacon, chairman of the American Committee of the American Ambulance Hospital in Paris, has issued a statement with reference to the new status of the work. The United States Army has taken over the institution, and it will be operated under the direction of the officers of the Medical Corps. It will henceforth be known as the American Military Hospital. Both the American Red Cross and the original ambulance organization in this country and in France will continue to work in harmony for its maintenance and operation. The institution has 575 beds, and up to August 1 the American contributors had sent $1,300,000. The French military control and regulations will continue with the American officers in charge.

Shelling American Ambulances.—A report brought from the front by a man who has served seven months with the Twelfth Section of the American Ambulance Corps, states that a new feature in the war since the United States has come in is the attack made by the Germans on American ambulances. This witness states that he has seen from twelve to sixteen shots fired at ambulances, but he has not seen the enemy score one hit.

National Census of Nurses.—The Council of National Defense, realizing that as the war progresses the shortage of nurses will become more acute than it is at present, has started a propaganda in cooperation with all the aid associations and national organizations throughout the country that have to do with professional nurses. Through these mediums a census of the visible supply is to be made. It is hoped in this way to learn the number of both trained and untrained nurses and those with special training in such fields as administration, teaching, public health and preventive work, industrial nursing, etc. This census is being obtained through the American Nurses' Association, working through its State associations. The committee reports that those who have first responded to the call for service contain a heavy proportion of nurses trained as executives, teachers, and public health workers, and these should be replaced largely through the colleges for women, through which it is hoped to interest a considerable body of potential nurses whose previous training should fit them for comparatively rapid training, thus enabling them to fill the vacancies which the war has created. Similar efforts are being made among the graduates of high schools and technical schools. Many of the larger hospitals of the country have decided to enlarge their training schools. Felix M. Warburg has aided the work by a gift of $5,000.

Hospital Ships Safeguarded.—The humane Kaiser has graciously sent assurances to the Spanish Government that British hospital ships are hereafter to be protected from attack by German submarines. Under the arrangement a neutral commissioner will be carried on each hospital ship to guarantee that it transports only sick and wounded. Seven Spanish officers have gone to France to act as commissioners on hospital ships.

APPLICATION FOR APPOINTMENT IN THE MEDICAL RESERVE CORPS, UNITED STATES ARMY

.....

....., 191

To the Surgeon General, U. S. Army,
Washington, D. C.

Sir:

I hereby make application to be examined for appointment in the Medical Reserve Corps, U. S. Army, and inclose testimonials as to my character and habits.

I certify that to the best of my knowledge and belief I am laboring under no mental or physical infirmity or disability which can interfere with the efficient discharge of any duty which may be required of me if appointed in the Medical Reserve Corps, U. S. Army, and that the answers given to the interrogatories below are true and correct in every respect.

I furtheromre state my willingness to proceed to such point for examination as may be designated by the Surgeon General, with the understanding that the journey entailed thereby must be made at my own expense.

INTERROGATORIES

Where were you born? (Give State and city or county; if foreign born, give country.).....

.....

What is your name *in full* (including your full middle name):.....

What was the date of your birth?.....

When and where were you naturalized? (For applicants of alien birth only).....

Are you married or single?.....Have you any minor children; if so, how many?.....

What is your height in inches?.....Your weight, in pounds?.....

Give the nature and dates of all serious sicknesses and injuries which you have suffered:.....

.....

If either parent, or brother, or sister has died, state cause and age in each case:.....

Do you use intoxicating liquors or narcotics? If so, to what extent?.....

Have you found your health or habits to interfere with your success in civil life?.....

What academy, high school, college, or university have you attended? State periods of attendance from year to year, and whether you were graduated, giving date or dates of graduation:.....

.....

Name and other educational advantage you have had, such as private tuition, foreign travel, etc.:.....

.....

Give all literary or scientific degrees you have taken, if any, names of institutions granting them, and dates:.....

With what ancient or modern languages or branches of science are you acquainted?.....

How many courses of lectures have you attended? Names of colleges and dates:.....

.....

When and where you graduated in medicine?.....

(Fill this out and send it to the Surgeon General, U. S. Army, Washington, D. C.)

Have you been before a State Examining Board? If so, state when, where, and with what result:*.....

.....

Are you a member of any State medical society? If so, give its name.....

Have you had service in a hospital? If so, state where and in what capacity, giving inclusive dates of each kind of service: .....

What clinical experience have you had in dispensary or private practice?.....

.....

Have you paid particular attention to any specialty in medicine; if so, what branch?.....

What opportunities for instruction or practice in operative surgery have you had?.....

.....

Have you previously been an applicant for entry into the United States service? If so, state when, where, and with what result (if rejected, state why).....

Are you a member of the organized militia? If so, state with what organization and in what capacity:

.....

Have you been in the military or naval service of the United States as cadet or otherwise? If so, give inclusive dates of service with each organization, designating it.....

What occupation, if any, have you followed other than that of student or practitioner? .....

What is your present post-office address?.....

What is your permanent residence?.....

Signature.....

The correctness of all the statements made above was subscribed and sworn to by the applicant before me this.....day of.....A.D. 191

[SEAL] .....

*This application must be accompanied by a certificate from the proper official that the applicant is duly registered to practise medicine in the State in which he resides.

Form 149

New York, August 25, 1917.

CONSCRIPTION UNNECESSARY.

A GOOD deal has been said lately, pro and con, regarding a proposition to draft physicians for the Medical Reserve Corps, the advocates of the plan alleging that the volunteer system has proved a failure, and that the full complement of medical men necessary to care for the new troops can be obtained only by conscription. While we have no objection to conscription as a principle, and, indeed, regard it as the best way to raise a large army, since it takes in all alike—patriots and would-be slackers, and does not favor the cowards and those who would live under the flag without paying for their privileges—nevertheless we do not want it for the Medical Corps at this time. Had the rule been made at the beginning that selection for the Medical Reserve Corps would be made by draft, it might possibly have been the wiser course, but to resort to conscription now for the reason that the quota of medical officers could be obtained in no other way, that the members of our profession were so lacking in manliness and true patriotism that they had to be kicked into line, would speak ill for us, would, indeed, put a stigma on the medical men of this country that time could not wipe out. We hope, and firmly believe, that this unwelcome step will not be necessary. As we have said before, men with family ties, with wife and children dependent upon their earnings for subsistence, however deep is their love of country, and however strong their desire to make the great sacrifice for her, must take time to provide for the care and maintenance of dear ones during their absence. But they are coming, a thousand a week, and with a little more effort on the part of the medical press (the recruiting officers) and a little fuller realization by us of what the country needs and expects of its medical men, who have always shown themselves ready for sacrifice and to be depended on in times of emergency and stress, the needed twenty-five thousand will be at call.

To those who can go, but are yet hesitating, we would commend a perusal of the letters to the MEDICAL RECORD from a medical reserve officer in one of the training camps. The letters do not treat of a picnic; the training is hard, of course, and one does not dine or sleep as he would in a Fifth Avenue mansion or an expensive hotel, but the company is good, and the men are honest and earnest in their patriotism and in their desire to do their part for their country and their fellows in the newly-filled ranks of the National Army. They are to be, and they are, envied by many who would gladly give themselves if they could be accepted; for it is a rare privilege, and those who cannot be taken know it. The professional experience is one that a medical man under 40 ought to give anything to acquire; the discipline is invaluable, and, however irksome at first, will benefit the man through all his life; the physical training will give a foundation of health that should last its possessor into green old age; and the opportunities that present themselves for the mental, moral, and physical betterment of the young and heedless recruits will, if embraced, fill one with happiness all his days. Then there's the adventure! Does not that appeal to the young physician? If not, he is unfit for his calling.

Our correspondent in the training camp says some men are there who have left motherless children at home; others have given up lucrative practices of perhaps thousands a year to accept a captain's commission with $200 a month; others again, who had begun to practise under the most favorable auspices, have left everything to obey their country's call. What then is to be thought of the young man without ties, and with only the hope of a practice, who lags behind and closes his ears to the cry of the wounded? What will he say, in the years to come, when his boy asks, "Daddy, where were you in the great war?" Will he say, "Oh, I stayed home and made money, so I could marry your mother"? Perhaps, if heredity counts, the boy will think that a good and sufficient answer. We don't believe there are many such among our readers; if there are any, we beg them to think again; their profession has ever been noted for the self-sacrificing spirit of its members, let them beware lest they disgrace it and bring upon it the stigma of conscription by their failure to do their duty. We print again an application blank, which should be filled out at once and sent to the Surgeon General at Washington by any one who is now ready to help in the most glorious cause that has ever been fought for by mankind; even the cause of American independence, the flame which lighted the torch of democracy, pales before the gigantic effort of the freemen of Europe and America to liberate the slaves of a hideous and inhuman autocracy. The man who can help in this is privileged indeed.

THE DECREASE IN DISEASE AMONG THE GERMAN FIGHTING FORCES DURING THE WAR.

IF we reflect that history is replete with instances of powerful invading armies being checked by disease and finally being obliged to give up their attempted conquests, we will not minimize the importance of military medicine to a fighting force.

Certainly the Germans have never failed to realize it. Long before the outbreak of war, their military surgeons knew exactly how the health of an expeditionary force could be preserved, and there is only one reason—albeit a good one—why Paris is not now under the most rigid Teutonic health control. We should expect, therefore, to find the health reports of the German army and navy as representing ideal conditions.

With this in view, let us glance at the figures presented by the *Deutsche medizinische Wochenschrift* in its issues for January 18 and February 15. During the first year of the war, that periodical states, the average monthly incidence of sickness in the army was 120 per 1,000; during the second year of the war it fell to 100. The highest frequence, according to this journal, was that of nervous diseases, 24 per 1,000; the next highest being pleurisy, 7.7 per 1,000. These figures are for the army. In the navy the number of diseases of the digestive tract were given as 56 per 1,000; and diseases of the respiratory organs, 36 per 1,000.

It is rather curious to note that the navy showed a much higher sickness ratio than the army. Thus, compared with the figures given above, it showed an incidence of sickness of 315.15 per 1,000 in the first year and 287.19 in the second year. To compare these figures with those during peace, we find that the average incidence of sickness for the five years preceding the war was 410.86 per 1,000.

Just why there should be such a marked decrease in sickness coincident with the onset of the war is difficult to say. It may be that emotionalism and the sense of being strung up to the highest point, which always occurs when a nation is at war, has prevented, to some extent, the habit of reporting sick from minor ailments. Such, at least, has been the case among the civilian population of the countries at war. Just as the call to battle may make a soldier forget a headache, toothache, or other annoyance of the kind, and plunge into the fray, so the feeling that the army is in active service, liable to be called into the fighting at any moment, makes the individual soldier hesitate to report hemorrhoids, hernias, varicoceles, and so on; his feeling being that these things can be attended to at any time.

Germany also reports a decided decrease in neurasthenia since the outbreak of the war. Of course, here we must consider that even among the neurologists, neurasthenia means one of two or more different things, depending on what school he follows, and that among the profession at large the term has been used to cover a multitude of symptoms and conditions. The chief connotation probably is a state where the patient suffers from fatiguability, insomnia, worry, and various transient subjective symptoms. It is roughly assumed that because there may be no organic basis found for these symptoms and because they may clear up for no apparent reason, they are all imaginary, and the doctor is too much inclined to look upon the patient with scorn, sometimes rather ill-concealed. The fact, however, that the frequency of neurasthenia dwindles so greatly on the occasion of a great national crisis is highly significant. It means that the neurasthenic has found an interest outside of himself. He is stimulated by an emotion which sinks into desuetude in peaceful times, namely, patriotism, and bends all his energies to serving his country. Thus his symptoms disappear.

So in Germany we find in both the army and navy a marked decrease in disease as a whole, but especially in minor ailments; whether this will be duplicated or not in our own forces remains to be seen.

THE DRAFTING OF MEDICAL STUDENTS AND HOSPITAL INTERNS.

THE Mayor's Committee on National Defense, through its subcommittee on Hospital and Medical Facilities, is doing a true work of national defense in its endeavor to prevent a cutting off of the supply of doctors by the draft. The conscription law makes no provision for exempting medical students and hospital interns, and one need not reason deeply to see that this omission, unless it can be remedied, will speedily produce a shortage in physicians that will affect injuriously not only the civilian population, but the army as well.

It would have been well could the framers of the law have been advised of the experience of our allies in this respect. At the beginning of the war England accepted as volunteers, and France conscripted, a large number of medical students, but within a year the unwisdom of this step became painfully apparent, and the students in the trenches and training camps were picked out and sent back to their studies. The same mistake is now to be made here, unless the Washington authorities can be convinced that it would be a fatal blunder. The Provost Marshal General seems to doubt the figures showing the havoc the draft will work in the supply of physicians, but Dr. Goldwater, the chairman of the committee on Hospital and Medical Facilities, is untiring in his exertions, and has succeeded in interesting the President and the Secretary of War, and has shown them that not only will the number of new physicians be reduced by the conscription of the senior students, but that the hospitals will suffer severely by the drafting of their interns. The Surgeon General, acting under instructions from the Secretary of War, is investigating the actual effect the draft will have on the student body and the hospital interns, and Drs. Wm. H. Welch and Victor C. Vaughan, both of whom are attached to General Gorgas' staff as special advisers, are directing the official investigation, and will have a hand in the framing of relief measures.

It is unthinkable that no remedy will be found to avert this peril. It may be that the law can be obeyed and at the same time the students be kept at their studies, by accepting them for service and then granting them furloughs until the completion of their education. Then, if the war continues, they can be assigned to the Medical Reserve Corps.

ESPUNDIA, BLASTOMYCOSIS, AND THE "SYPHILIS OF THE INCAS."

In a valuable monograph by Escomel on leishmaniasis (Buenos Aires, 1917) we note some photographs of ancient Peruvian statuettes with mutilations of the face, which, if we mistake not, have already been made to serve as documentary proof of the existence of a destructive type of syphilis in the prehistoric Peruvians. The author, who does not even mention the possibility of this disease in this connection, feels quite justified in the belief that such lesions were due to espundia, a clinical type of leishmaniasis. He compares these figurines with present day patients who show the very same type of mutilation; and infers that espundia is a disease of remote antiquity in South America. Very similar in clinical expression to espundia and sometimes associated with it is a form of blastomycosis. Aside from the different causation the two affections are readily differentiated by the treatment test; for while espundia is favorably influenced by arsenic (salvarsan) and antimony, blastomycosis has no treatment other than surgical.

Leishmaniasis occurs in the entire Western Hemisphere south of the Rio Grande river although it does not reach the dignity of a serious folk malady until it arrives at the latitude of Bolivia, Peru, and Brazil. It now begins to receive special local designations, such as espundia (in Peru), Bahia button, Baurú ulcer, buba, uta and even frambesia and pian. Escomel shows that the earliest descriptions of frambesia in South America must have included espundia while the word buba has at various times done duty for syphilis, frambesia, and in fact the entire group of destructive lesions about the face and elsewhere. Blastomycosis is much more restricted geographically and has its chief incidence in Peru, Bolivia, and parts of Brazil. The only directions laid down by Escomel for excluding syphilis, yaws, etc., in diagnosis refer to bacteriology and treatment. Syphilis and yaws, in addition to serological and bacteriological criteria, yield rapidly to salvarsan, much more rapidly and thoroughly than does espundia. Neither the latter nor blastomycosis is spread by venereal contact, although both begin as a so-called "chancre" and exhibit not only secondary manifestations but perhaps even others which could be termed tertiary. The term "secondary" applies primarily to lesions involving the mucosæ, which are never attacked primarily. The initial lesions are probably due to the bites of insect carriers on exposed areas. In theory at least and from analogy and animal experiment the particular species of leishmania and blastomyces can attack the viscera.

It is of course possible that syphilis existed among the ancient Peruvians, but the work of Escomel shows plainly that the facial mutilations in the native pottery figures point at the outset to espundia or blastomycosis and that one link in the chain of evidence for syphilis is thereby broken or at least weakened. The labors of Cruz, Chagas, Escomel, and other eminent South American bacteriologists and parasitologists has already done much for the history of pathology. This school of scientists seems at present little concerned with the vague past but doubtless the time will come for clearing up certain problems of disease by a research into historical archives.

Genesis of Malaria.

The mere presence of the freshly inoculated plasmodium in the human blood is not, *per se*, sufficient to set up malaria, but the so inoculated subject becomes forthwith a carrier of the disease. When the disease does develop it is after an incubation period of from 10 to 15 days. In a valuable article by Garin, abstracted in the *Journal de médecine et de chirurgie pratiques* for July 25 this aspect of malaria is thoroughly considered as based upon studies at the Macedonian front. Of a large number of soldiers who carried the plasmodium in the blood, from 60 to 80 per cent. showed no infection, and were able to render normal service. Repeated examinations showed that these men had acted as hosts over long periods of time. For an infection to occur, the plasmodium must multiply rapidly in the blood and destroy many erythrocytes, and this form of immunity which is so commonly in evidence means that some factor inhibits the multiplication of the microparasite in the blood. It is, of course, possible that instead of a natural immunity there is a rapidily improvised defence in which some antibody is enabled to dissolve the parasites through the formation of a lysin. The result is a partial acquired immunity and the lysin therefore behaves as a "natural quinine." When men become infected there must be a *tertium quid*—either muscular fatigue, exposure to the sun, alcoholic intoxication, wounds, or surgical interventions. Experience teaches us that these factors can each and all favor the development of malarial infection, and this fact connotes injury to the defensive forces, as already outlined. A new and important factor has come to light on the Eastern Front, to wit: chloroform anesthesia, which is known to be prejudicial to the hepatic functions. Since the sequence, chloroform-malaria, has been established, ether anesthesia has been substituted. Antityphoid inoculation may or may not predispose to an acute malarial explosion. The month of November must be mentioned in this connection as a factor, although the effect of cold weather on the mosquito cuts off the source of infection. Exposure to cold and damp, irrespective of the month, appears also to damage the natural defence and determine an outbreak of the disease.

Malingering

The European war will doubtless increase the old literature of simulation, artifacts, malingering, and allied subjects manyfold. Doubtless the twins, Slacking and Simulation, are a necessary offspring of military conscription. The monotony of articles on this subject is wearisome, for there is no limit to the possibilities of this form of playing possum. It is said, doubtless with more or less truth, that a physician whose training has been chiefly military

is prone to look on his civilian patients as at least potential malingerers. In *Il Policlinico* of June 3 there appears a symposium on simulation. In the first place, Professor Ascarelli contributes an illustrated paper on self-inflicted injuries, which he terms autolesions. These comprise eschars, ulcers, abscesses, contusions, etc., produced by various caustics and other means on the hands, feet, and legs. The ear is also a favorite locality for the production of these lesions. This article is followed by one from Professor Condorelli-Francaviglia on conjunctivitis produced by the seeds of the castor oil plant, which contain ricin, a notable irritant. Professor Bilancioni follows with an article on detection of the simulator of bilateral deafness.

News of the Week.

The Mortality Rates and the Hot Wave.—The *Weekly Bulletin* of the Health Department of New York City makes a comparison of the death rates of the weeks ending July 28 and August 4, and finds a difference of 955 deaths, which it believes are attributable to the excessive heat of the week ending August 4. It also makes a comparison of temperature, humidity, and mortality rates with the excessively hot week ending July 6, 1901, and finds that the death rate at that time was more than twice as great as during the week just passed. The deaths reported as directly due to sunstroke or heat prostration during the hot week ending July 6, 1901, numbered 989 as against 358 for the recent hot week. The number of horses that succumbed to the heat was unprecedented. In ordinary periods, about 200 dead horses are removed from the streets each week, while during the week ending August 4, 776 were removed.

July Street Accidents.—There were, according to the official report of the Police Department, 2,461 accidents in the streets of New York during July, with 2,718 persons killed or injured. This was an increase over June. The number of deaths for July was 53 males and 21 females, as against 48 males and 9 females in June. During July, Saturday showed the largest number of accidents of any day in the week, and accidents were most numerous between five and six o'clock in the afternoon.

Infantile Paralysis in Pennsylvania.—On August 13, the presence of infantile paralysis in two sections of Pennsylvania was reported to the State Department of Health. Twenty-one cases were reported at Newcastle and the vicinity, and 34 in Lancaster County.

Straus Memorial.—At a recent meeting in the offices of the East Side Protective Association a committee was chosen to formulate plans for the erection of a suitable memorial to Nathan Straus in appreciation of his twenty-five years' service to the children of New York City in furnishing free milk through his milk stations. The memorial is to be erected in Seward Park, Hester and Essex Streets.

Municipal Meals in Hamburg.—A report to the *New York Times* states that more than 180,000 residents of Hamburg are now being fed at the municipal soup kitchens, owing to the difficulties of obtaining food for individual households. In April, May, and June, between 230,000 and 240,000 persons daily visited the kitchens for their meals, and it is expected that the number will again increase during the coming winter. These figures do not take into consideration school children fed at the school canteens. The death rate during the month of June was 49 per cent. higher than the birth rate. The excess of deaths has fallen at the present time to about 30 per cent. higher than the birth rate.

Bequests.—Mount Sinai Hospital and Montefiore Home and Hospital, New York, and Zion Home, Buffalo, are each the recipients of $1,000 under the will of Norbert Gunzburger.

Venereal Clinics Extended.—The Department of Health of New York City has established Venereal Advisory Clinics in each of its four Health Centers of the Borough of Queens. Each clinic has two consultation days a week. The medical advisor will consult only with those applicants who are not under the care of a physician and who come to the Health Department seeking advice regarding venereal diseases. Under no circumstances will patients be interviewed who are sent by physicians or private institutions for the Wassermann and complement fixation tests, unless request for advice be made by the physician or institution sending the patient. All applicants are given a circular of information regarding venereal diseases and a card of instructions regarding syphilis and gonorrhea. It is promised that the histories taken are kept confidential.

Dr. S. R. Klein, formerly professor of histology and embryology at Fordham Medical School, has been appointed assistant superintendent, pathologist and roentgenologist to the Waldheim Park Sanatorium, Oconomowoc, Wis.

Rear Admiral Charles F. Stokes, U. S. N., retired, has resigned the position of medical director of the Warwick Farm for Drug Addicts.

Dr. Aristine P. Munn-Recht has been appointed as the first dean of women at New York University.

Albert Calmette, director of the Pasteur Institute at Lille, and founder of the Pasteur Institute in Indo-China, has been called to Metchnikoff's vacant place at the Pasteur Institute in Paris.

Bribe Takers Punished.—Two members of a local exemption board in New York City, a physician and a druggist, have been sent to the Federal prison at Atlanta for two years for having accepted money from drafted men to pronounce them medically unfit.

The Clinical Congress of Surgeons of North America, which was scheduled to hold its annual meeting in New York, has changed its plans. Preliminary plans have been made for a "War Convention" to be held in Chicago during the week of October 22.

The American Public Health Association Congress that was to have been held in New Orleans in December has decided to meet in Washington, D. C. This is because war hygiene is a subject of such importance at the present time that the congress believes it can better help solve the war problems from the sanitary standpoint by making this change.

Alabama Medical Association Adopts Re-

ciprocity Agreement.—At a meeting of the Alabama Medical Association, held in Montgomery on August 4, a reciprocity agreement was adopted whereby licensed physicians of the States of Ohio, Arkansas, Louisiana, Pennsylvania, Kentucky, Oklahoma, and Mississippi, may practice in Alabama, or Alabama physicians may practice in any of these States. The provisions are that the physicians in such a case must present credentials, must have passed his State examination, must have practiced medicine two years, must be a member of the medical society of his State, and must be a graduate of a Class A medical college.

French Embargo on Magnesia.—The American Consul General at Paris has sent the following cablegram: "Decree of August 7, published August 9, prohibits export, etc., from to-day of magnesia and carbonate of magnesia." The decree is subject to the usual exceptions.

Obituary Notes.—Dr. HENRY FREEMAN WALKER died from heart disease at his summer home in Pittsford, Vt, on August 12, at the age of 80 years. He was a graduate of the College of Physicians and Surgeons, New York, a member of the New York Academy of Medicine, and consulting physician to St. Luke's Hospital. He retired from active practice in New York City several years ago.

Dr. HOSEA ELLSWORTH WALKER, a graduate of Bellevue Hospital Medical College, in 1892, and visiting physician to St. Vincent's Hospital, died at his home at Fort Wadsworth, Staten Island, N. Y., on August 16, aged 52 years.

Dr. RALPH B. GRISWOLD, a graduate of the Eclectic Medical College, Cincinnati, in 1857, died at his home in Banksville, N. Y., on August 1.

Dr. ALBERT L. BINGHAM, a graduate of the University of Vermont in 1875, died at his home in Williston, Vt., after a lingering illness, on August 6, at the age of 64 years.

Dr. LEVI P. ESSLINGER of New Market, Ala., a graduate of the Birmingham Medical College in 1903, died after a surgical operation in a Nashville hospital, on August 6, aged 40 years.

Dr. WILLIAM LOWNDES WELLS died of pneumonia at his home in New Rochelle, N. Y., on August 17, at the age of 87 years. He was a graduate of the College of Physicians and Surgeons and of Heidelberg University, in 1852, served as a surgeon in the Union Army during the Civil War, and was afterward associated with Dr. Janeway and Dr. Thomas Addis Emmet. He retired from active practice about twenty years ago.

Correspondence.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

REGIONAL ANESTHESIA

PARIS, July 17, 1917.

PROBABLY there is no ten years in the history of surgery that show the variety and extent of progress that has been made evident since the outbreak of the present great war, and one of the innovations that promises lasting good is the steadily growing practice of regional and local anesthesia replacing the use of ether and chloroform.

For thirty years Professor Réclus of the Paris Faculté preached and practised local anesthesia. His method consisted in infiltrating the tissues upon which he proposed to operate, with a feeble solution of cocaine and proceeding with his operation. The chief inconvenience of this procedure is that often the effect of the anesthetic does not last long enough to complete the operative procedure, and the operator must arrest his work to reinject and insensibilize the field; this form of anesthesia is, however, well known and much practised in France, and out of it has grown the idea, and from that the experimental investigation which has perfected regional anesthesia.

My friend and colleague, Dr. Victor Pauchet, professor at the Amiens Medical School and at present head of two services of war surgery in Paris, is one of the leading exponents of this new procedure. He is a man of charming presence, one of the ablest of the present-day operators, and Americans are welcomed to his operations and afforded every facility to study his methods and especially his anesthesia by injection, which he can explain as well in English as in French.

The knowledge and practice of regional anesthesia have progressed to the extent that the method covers every anatomical area and under its influence all of the major as well as the most delicate of the minor operations are permitted. By its practice we have overcome the noticeable shock following the operations upon the vital organs so frequently met with after the use of the ethylic compounds. The nausea and vomiting which sometimes endures for forty-eight hours after an operation and is a prominent factor in the depression of the vital force, and, when the strength of the patient has been wasted to the last degree before submitting to operative interference, is often the determinating cause of death, is done away with. Regional anesthesia differs wholly from the method of Réclus, in that it is a form of anesthesia that its name implies, whereas it consists in injecting the nerve at its point of origin or along the trunk near the point of origin, and as a consequence all of the field supplied by such nerve is rendered insensible.

Réclus' method presents the inconvenience that frequently the effect of the local anesthesia subsides and the operator has to interrupt his operation to reinject and insensibilize the tissues before proceeding; whereas in regional anesthesia the effect of the injections endures for one and one-half to two hours, long enough to complete the most complicated of operations. There is no danger to the life of the patient from the effects of the injections, while it sometimes happens that the subject dies under the influence of general narcosis.

The effects that sometimes appear as complications in the lungs, liver, and kidneys following general narcosis, are absent in regional anesthesia and in this respect the superiority of regional anesthesia over ether and chloroform is made strikingly apparent in operations in the presence of chronic icterus or of renal insufficiency; and equally the advantages of regional anesthesia in respect to shock are pronounced when comparison is made between a series of cases of cancer of the stomach operated upon under narcosis and under anesthesia by injection.

Operations upon the respiratory tract or in the

near neighborhood are greatly facilitated. The patient assumes any position desired, being fully conscious; he can at will arrest his breathing, suppress a cough, or expectorate if needs be. This is a valuable aid to operations upon the pleura, larynx, neck, etc.

Regional anesthesia is, of course, very well known in America, but it has not made as rapid progress there as in Europe, because, I think, of lack of precise knowledge regarding the details of its regional application and technique, and because an idea prevails that it requires a special knowledge and aptitude for its application, whereas in Paris the injections are made for the operator by the interns and hospital nurses.

2. A Study of the Urines of Picric Acid Workers.—F. O. West states that the medical complaints of men engaged in the manufacture of picric acid having been treated in a general way, this investigation conducted by him was undertaken to determine the truth of the popular belief that the kidneys are seriously affected in those constantly exposed to this substance. The employes examined were working under hygienic conditions as far as suitable buildings, hours, and care were concerned. Examinations were made on the urines of the entire crew of picric acid workers, including machine operators, packers, men handling the dried powder, and the steam fitters whose duties were confined to this department. The crew was made up of both whites and negroes. The length of service varied from one to eighteen months. On careful questioning no evidence of a symptom-complex was found that could be attributed to picric acid poisoning. The urines were examined for the presence of albumin and picric acid. The following tests were used for the detection of albumin: heat and acetic acid with filtered urine. Picric acid: three tests were applied to all urines—white wool, copper sulphate, and potassium cyanide. The result of this investigation tends to show that picric acid may be manufactured without great hazard to the employee, provided the work is carried on under proper conditions and the men are subjected to rigid medical supervision. Of 86 urines examined for the presence of albumin, 3 gave the "slightest possible trace" at the end of employment, whereas it was not detected at the outset. Nevertheless, these three men had never been affected by any of the substances they were handling; while many men not given the test had been repeatedly treated, one of this latter class having nearly died from the effects of fume poisoning. In addition to the examination for albumin, 57 of these urines were tested for the presence of picric acid, and three were positive. Unfortunately, the value of this information is open to suspicion, on account of possible contamination. If the picric acid had been excreted in the urine in these cases, the writer found no evidence of its having caused renal irritation.

4. Diagnostic Teeth.—Percy Willard Roberts states that there is abundant evidence that the value of the teeth as an aid in the diagnosis of certain morbid states, notably bone and joint lesions, is very much underrated. He has observed during the last few years numerous cases of inherited syphilis which had undergone long periods of treatment based upon incorrect diagnosis and in which inspection of the teeth with an intelligent interpretation of the findings would have given a clue to the true pathology and shortened immeasurably the period of invalidism. Unfortunately anomalies of the teeth are usually looked upon as the special charge of the dental surgeon, their clinical significance being little understood. Outside of the classical Hutchinson teeth, not a great deal is known among medical men about other forms of syphilitic teeth. That the abnormal tooth formations seen in hereditary syphilis are not merely an expression of a general dystrophy, but are more often the result of local inflammatory disturbance, due to the immediate presence of the spirochetes, is suggested by the fact that the organisms have been recovered from the dental structures of the dead fetus. Syphilitic activity must correspond, not to the period of eruption of the teeth, but to the time during which they are undergoing calcification. The first permanent molars begin to dentify during the sixth month of intrauterine life and the incisors and canines during the first three months after birth. In addition to the recognized syphilitic tooth conditions as described by Hutchinson, Fournier, Moon, and others, there are other anomalies of form and arrangement of the teeth frequently seen in inherited syphilis which may have an important bearing on clinical diagnosis in both medicine and surgery. Fournier estimates that fully 80 per cent. of these conditions are produced by syphilis and the balance by other causes which may be unknown, but from which syphilis cannot be definitely excluded. Absence of dental units is a common form together with symmetrical erosions of various kinds, anomalies of spacing, white sulci, and the tendency to early decay. The writer emphasizes the value of an otherwise trivial dental anomaly as a clue to the pathology of an active lesion elsewhere in the body. Particular attention is called to abnormal spacing between the two upper central incisors, which, when occurring alone, has not been regarded as of diagnostic significance. The fact remains that it is so often present in recognized cases of syphilis. It may be the only dental irregularity in a subject of inherited syphilis and has in Roberts' experience been the means on many occasions of detecting syphilis which had been for years overlooked. Eleven cases are cited showing the presence of this condition in both boys and girls and adults. In conclusion, let it be repeated that the typical Hutchinson tooth, with which we are all familiar, is but one of many types of dental deformity produced by inherited syphilis. The very nature of the disease, most active as it is during the period of tooth formation, may produce an infinite variety of abnormal dental shapes and arrangements, the presence of any one of which when associated with disease in other parts of the body should arouse suspicion as to the pathology of the active process where positive evidence of its nonsyphilitic origin is lacking. To ignore these signals of hereditary taint which nature has placed so conspicuously before us is to invite diagnostic disaster.

12. **Intubation of the Larynx: An Analysis of Three Hundred and Fifty Cases in Private Practice.**—Henry James Cartin points out that laryngeal diphtheria, requiring intubation, has been considered by most pediatricians as a disease for hospital treatment. It is because of this belief that he decided to present an analysis of 350 cases occurring in private practice in the hopes that results obtained under the most adverse conditions may lead to more general use of this operation when hospital facilities are lacking. Johnstown, Pa., where the treatments were carried out, is the center of vast steel and mining industries which attract a large population of laboring people of both native and foreign birth. The homes of many of these are overcrowded and living conditions are unhygienic, resulting in many of the children having chronic catarrhal conditions of the upper respiratory tract. There is concealment of disease through fear of quarantine, and exposure to disease through ignorance of contagion and indifference to it. These conditions made a fertile field for epidemics of laryngeal diphtheria during the years 1905-1917. The increase in the number of cases intubated is due primarily to the epidemics and secondarily to increasing knowledge among the physicians of the success of the operation so that each child was given the chance of intubation if needed. The conditions for operation were far from satisfactory. For operating, the kitchen table, bed, or two chairs were used; in one case the door. The light was always poor. A parent, neighbor, or physician usually held the child. The physician, through interest in the operation, frequently failed to hold the child properly. The other helpers failed through nervousness. His results have given him the following facts: (1) No patient needing intubation should be denied the chance to live because of lack of hospital facilities. (2) Overcrowding of homes, unhygienic surroundings, concealment of disease, and exposure to contagion are responsible for the epidemics. (3) Lack of trained assistants need not deter one from operating. (4) The use of a tube larger than that indicated for a given age gives better results. (5) Early intubation with large doses of antitoxin reduces the mortality. (6) Wearing the tube five days resulted in fewer reintubations. (7) It appears that special diet and methods of feeding are unnecessary. (8) Reintubation does not seem to affect phonation permanently.

1. **A Report on the Treatment of 102 Carriers of Amebic Dysentery with Emetine Bismuth Iodide.**—W. Waddell, C. Banks, H. Watson, and W. O. Redman King state that the cases dealt with were discovered to be carriers of *Entameba histolytica* in the course of the ordinary routine examinations of feces at the hospital where the examinations were carried out; none of them were found to be carriers of dysentery bacilli. They were all treated with emetine bismuth iodide, and the results were such as to demand publication, as this is the first time, as far as the investigators know, that the drug has been tested on such a large scale. The treatment has had the advantage of being carried out under the supervision of one medical officer at a place where the necessary protozoological examinations could be made on the spot. The results of the treatment are as follows: (1) Emetine bismuth iodide is much more effective than emetine hydrochloride in the treatment of carriers of *Entameba histolytica*, but about 20 to 25 per cent. of failures may occur. (2) The intensely irritating properties of the drug in many cases are a drawback in its general application. (3) The definite failure to cure 19 out of the 102 cases treated at Barton may perhaps be in part due to the form of the drug employed (a keratin-coated tabloid). (4) It is improbable that there were many relapses later than those discovered; and as several of the cases had only eight or nine doses instead of 12, it seems likely that less than 36 grains may be effective. (5) It is advisable to keep cases under observation for not less than 14 days after treatment, and to examine them not less than four times during that period if relapses are to be detected. (6) The drug is without appreciable effect upon the intestinal flagellates, but has an effect, usually temporary, on *Entameba coli*.

5. **The Premeningitic Rash of Cerebrospinal Fever.**—C. P. Symonds states that various observers have noted that there may be an erythematous rash in cerebrospinal fever. Rolleston, in a recently published series of 95 cases, mentioned it as occurring in 5, while in another 5 there was a so-called rose rash; but no one, as far as Symonds is aware, has remarked upon the time relations of this eruption (a) to the onset of the illness, and (b) the first symptoms of meningitis. In a fair experience of the disease (about 50 cases) he has seen this erythematous rash in three cases; it was in each instance observed very early after the onset, and before there were any symptoms of meningitis to suggest the diagnosis, so that it is perhaps worth recording the details. Three cases are given. In Case I, where the patient was under observation from the onset, there was a profuse rash to be seen six hours later, which had disappeared four hours after it had first been observed. This case, a private, aged 32 years, was in the hospital for five days for dyspepsia; there were no physical signs of organic disease. At 2 A. M. he woke up with a fit of shivering, complained of headache, vomited, and was restless. His temperature later in the morning rose to 102°, and when examined at 10 A. M. he showed a profuse rash on the chest, abdomen, and back. This rash consisted of erythematous spots of about the size of the finger nail, which faded on pressure, and were just distinctly papular to the touch. There were no physical signs except a little sticky pharyngitis. Kernig's sign and neck stiffness were not present. Later in the morning his rash began to fade on the trunk, and to appear on the arms and legs, and by 2 P. M. had disappeared altogether. At 3 P. M. a specialist diagnosed the case as one of malaria. At 5 P. M. the patient was irritable, complained of pain in the back of the neck, and showed

a positive Kernig's sign. Lumbar puncture performed at 7 P. M. yielded fairly turbid fluid under pressure, containing meningococci and pus cells. In Case III the erythematous rash was present twelve hours after the onset and had almost disappeared six hours later. In Case II the probability is that there was primarily a local meningococcal infection of the throat and nasopharynx, and that this became a general infection after the patient's admission to the hospital. Twelve hours fater the onset of illness the rash was observed and seven hours later the fine, typical rash had replaced the first one, and the patient had developed signs of meningitis. Probably in all three cases the rash had made its appearance and faded away within twenty-four hours of the onset of the general infection, and it was certainly a striking feature of each case before meningeal symptoms suggested the diagnosis. These cases tend to confirm the hypothesis already advanced by investigators that there is a septicemic stage in cerebrospinal fever which precedes the meningitis.

4. A Case of Acholuric Jaundice. W. H. McKinstry.

3. Medical and Surgical Notes from Mesopotamia.—G. Grey Turner gives a résumé of some of the disease conditions encountered among the troops in Mesopotamia. The cases coming under the heading "Effects of Heat," though interesting, were depressing and disappointing, for so very often treatment was unavailing. He states that he shall not soon forget the stream of patients in June and July who were hurried to the bath house, nor the occasion when nearly a dozen stertorous patients lay in the open air along the side of the creek, many of whom went to make up the sixteen funerals that left the hospital the next day. These men were not weaklings, but often big, strong fellows who might be expected to be the last to go under. Nearly every case illustrated the importance of prophylaxis and of early treatment, and those that developed in hospital often recovered as the result of prompt measures to reduce the temperature. But the heat regulating centers are so much deranged that relapses are common, and there can be no doubt that anybody who has suffered from a severe attack should be sent out of the country. Postmortem examinations in these cases were disappointing, the appearances were not uniform or characteristic, and there was much less cerebral or meningeal mischief (to the naked eye) than was expected. The congestion of the internal viscera which was always found was only a consequence of the slow process of dying from coma. Turner further states that there is a great deal of work to be done on these cases, and until their minute pathology and chemico-pathology is better understood the methods of treatment must be empirical and haphazard. Prophylaxis is the most important thing, and the responsibility for the transport and care of troops coming fresh to a moist, hot climate like Basra in May, June and July, must always be great. Every detail must be attended to, and the soldiers must be tended like ignorant children, and no point is too small or trivial to be neglected. As a result of conversations with men who had suffered from the effects of heat in its various forms, Turner is satisfied that those who tolerate heat badly at home should not be sent to this climate. New troops, and especially their officers, coming to tropical countries, should be educated as to the precautions necessary. Newcomers revel in the sun and suffer; they should be told that the sun is an enemy to be avoided, that the head and back of the neck should be covered, and that advantage should be taken of every little bit of shade. He concludes by stating that it takes some time before one instinctively walks at a funeral pace and seeks the most trivial of shades. Men should never leave camp without their water-bottles, and every care should be taken to avoid exhaustion.

Le Progrès Médical.

July 21, 1917.

Adrenal Dyspepsia.—Loeper, Beuzard and Wagner first mention the gastrointestinal troubles of Addison's disease, such as almost permanent anorexia, atonic dyspepsia, and constipation, with occasional exacerbations of vomiting and gastric and intestinal crises. These symptoms may appear in a restricted degree in the overworked and in the convalescent soldier as a result of adrenal insufficiency. Adrenal dyspepsia is not very painful in type. At any time from a half hour to two hours after eating we note the presence of aerophagia and gastric distention. Constipation is persistent and obstinate, with occasional reactionary crises of diarrhea. Paroxysms of colic and vomiting are rarely seen. There is often much emaciation proceeding from lack of aliment due in turn to permanent anorexia. There is absolutely nothing to implicate the adrenals. Analyses of stomach contents and stools, and the *x*-ray, bring out nothing characteristic. There is often low blood pressure, which could readily be the result of the condition, and not necessarily due to adrenal hypofunction. This is equally true of Sergent's white line. Asthenia is not extreme and melanoderma seldom present. Certainty is only found in blood analyses and in the results of treatment. The former are naturally attended by difficulties and are unnecessary when the treatment test is so readily applicable. Injections daily, or every other day, of a half or one milligram of adrenalin often are productive of the most surprising results, even although in many cases no benefit accrues. The third injection may be followed by complete restitution of function. In such cases we see the blood pressure rise and the asthenia disappear; and there seems no room for doubt that there is such a malady as "capsular dyspepsia," and that we have cured it. The mechanism is still obscure, because we do not know to what extent the sympathetic and cerebrospinal nervous systems, smooth and striped muscle, and glandular cells are individually acted upon by the drug.

Butyric Dyspepsia.—Chevrel has studied this subject in the young child in connection with mucous gastritis and pylorospasm. Cantley, the English pediatrist, has been a pioneer in the study of a condition which can simulate pyloric stenosis. It appears to be determined by an unbalanced and defective diet, too rich in fats, and improves when this dietetic fault is corrected. The author narrates the case of a nursling who took the breast well but could not gain weight. Artificial feeding produced no better result, no matter how varied. The patient often vomited the food and alternated between constipation and diarrhea. Examination for pyloric stenosis gave negative results. Butyric acid odor was apparent in the vomitus. When about four months old the child was losing weight. Among the food articles tested were homogenized milk, rennetized skim milk, legume purées, milk cut with mineral waters, panada, buttermilk, casein (fresh cheese) in sweetened milk, etc. All of these fat-free foods were ill borne. The baby was now a typical athreptic, with grave outlook for recovery. At this juncture it was noted that an immense amount of mucus was being vomited, and lavage was begun, with most striking results. Vomiting ceased, the diet at the time comprising rennetized skim milk and new cheese. Upon this food, with occasional lavage, weight was rapidly put on.

Familial Appendicitis and Hereditary Syphilis.—Gaucher and Brenet report the following episode: A ten year old girl presented herself for pain in the side, and was found to have appendicitis. It was learned that she had been cured two years before of an interstitial keratitis with mercury. Her physique was excellent, save for slight evidences of lymphatism. There were further stigmata suggesting syphilis, and a positive Wassermann. There had been eight children in her family, patient the seventh. One older sister died at 18 years, had had chronic appendicitis, and another died at 20 of perforative appendicitis. A third died at 15 years of appendix-peritonitis. Two boys

died early in life, causes inconsequential. There is another sister, age 13, who has been operated on for appendicitis. The youngest of the family, a boy, died early in life, no cause stated. Parents both known to have had syphilis. This is Gaucher's fourth syphilitic family in which appendicitis is known to have developed in familial incidence; and these do not include others in which appendicitis developed in the third generation of syphilitics.

Silent Peritonitis and Sudden Death.—Minet describes three cases of this sequence. I. A soldier, aged forty-six, was found dead in his bed at 2 A. M. The evening before he had gone to the regiment surgeon complaining of painful urination. Pus and albumin were found in the urine, and he was told to await a complete analysis. His comrades said that he had seemed well the day before, had eaten dinner as usual, and gone to bed at the regular hour. The cadaver showed no sign of violence. Examination of encephalon and thoracic cavity negative. When the abdomen was opened about a quart of reddish fluid escaped. The peritoneum of the abdominal wall and intestines was covered with abundant false membranes. The small intestine was constricted at one point. One kidney presented a tuberculous nodule. The bladder was filled with pus. II. This soldier was also aged forty-five, and consulted the surgeon for cough and dyspnea of recent onset. He was at once interned and his chest found to be the seat of extensive râles for which numerous wet cups were applied. Neither these nor cardiac stimulants arrested the symptoms, and patient died next day. As he had been exposed to dinitrophenol it was held that death had been caused by edema of the lungs. The cadaver showed intense icteric hue. The head and throat showed no lesions. The lungs showed marked congestion but no edema. There was recent pericarditis and the cardiac cavities were filled with coagulated blood. The abdomen was filled with pus and false membranes. The appendix was constricted and its free end filled with pus in which lay a fecal concrement. Patient also presented the large white kidney. III. This was an old case in a civilian who had been kicked in the abdomen during a fight. He was able to walk a short distance to his home, where he made out a complaint. He went to work as usual next day. On the fourth day, after a little malaise, he vomited, collapsed, and death ensued. Autopsy showed no evidence of external violence (the assailant was acquitted of manslaughter) but there was an enormous amount of pus and fecal matter in the abdomen due to a double rupture of the small intestine.

Experimental Researches on the Cytologic Formula of Serous Effusions in the Tuberculous.—Golay, assistant of Professor D'Espine in the Geneva pediatric clinique, has attempted to determine whether or not serous effusions in the tuberculous have a characteristic cytologic formula. The first patient to be tested was a boy of 13 who had a fibrocaseous tuberculosis of the right apex. He developed symptoms of meningitis, but the spinal punctate was sterile. Meanwhile it became evident that a pneumococeus pneumonia was in evolution. This ended favorably by crisis. The memingitis symptoms persisted for a short time and then subsided. The punctate was still sterile. The cell count of the punctate had shown much variation. At the onset of the meningeal symptoms there were 300 elements, almost entirely lymphocytes in the Nageotte chamber with albumin 0.25 per 1,000. After the pneumonia crisis there were 120 lymphocytes with albumin same as before. After complete recovery there were 3.4 elements per mm., albumin 0.15 per 1,000. The investigation was then transferred to rabbits of two groups, healthy and tuberculized. The principal difference noted was during the early hours of the experiment when the tuberculized animals showed a relatively larger presence of mononuclears. This corresponds in a measure to the cell counts of blister fluids in sound and tuberculous subjects, the latter showing from 14 to 20 per cent. more mononuclears than the former. This holds good for fibrocaseous phthisis, not for advanced cavitary phthisis with secondary infection.

Poisoning by Rhubarb Leaves.—Maillart relates an episode in the belief that it is almost unique—familial poisoning with the leaves of garden rhubarb — which had been eaten as a part of spinach dish. The author refused to believe that the symptoms could have been due to rhubarb leaves. On investigation he found that such a sequence is on record with two fatal cases. The conditions were the same—rhubarb leaves had been eaten with others as "greens." The author then investigated his own cases carefully. The parents, their four children—from 8 to 13 years of age—and the domestics, all ate the greens together and a few hours later developed a violent diarrhea. All recovered rapidly excepting the father, who continued to suffer with digestive disturbances, somnolence and prostration. When seen 8 days after the intoxication his nutrition seemed intact and nothing was found on examination until the urine was reached when 2¾ per 1,000 albumin was revealed. Although the patient made a good recovery, it was evident that he had passed through an epithelial nephritis. An old lesion of the kidneys could be excluded. This association of gastric, nervous and renal disturbance points at once to oxalic acid poisoning. One of the fatal cases, which occurred in an English clergyman, was proved to have been due to the ingestion of rhubarb leaves which contained 1½ per 1,000 of potassium oxalate, a toxic salt of oxalic acid.

July 14, 1917.

Influenza Meningitis.—Tobler speaks of the not infrequent association of suppurative meningitis with influenza. We do not as a rule know whether this complication is due to Pfeiffer's bacillus or one of the ordinary pyogenics. In seeking to throw light on this subject the author studied a case in great detail. The patient was an infant 5 months old with congenital syphilis. It passed safely through a sharp attack of influenza and then underwent an inunction cure. Some weeks after recovery from influenza meningeal symptoms suddenly appeared. Culture tests of the spinal punctates were negative throughout but hemoculture yielded Pfeiffer's bacillus. Despite the threatening character of the meningeal sequela death occurred apparently from intercurrent acute peritonitis. Autopsy revealed purulent basal meningitis of base and convexity with an accumulation of pus in the peritoneal cavity along with ordinary adhesive peritonitis. In pus from both sources Pfeiffer's bacillus was found under the microscope in advance of cultures. This case goes to reinforce a certain number of others on record, chiefly in young infants, in which the meningeal complication or sequela was evidently not due to mixed infection. In such cases the meningitis is doubtless not due to metastasis but to direct extension of the infection.

Attempts at Cure of Amnesia by Means of Free Association and Hypnosis.—Rorschach relates this case: A soldier sent home on furlough did not return on time. Investigation led to his discovery in a beer cellar in a state of mental confusion and amnesia. Removed to the hospital he was able to remember up to a certain hour on the first day of his furlough when apparently he had met with an accident. He was able to give a good history of himself and family, and had never before been in a twilight state although there may have been an unmotivated tendency in boyhood to wander. He had always been alcohol-intolerant and two glasses of beer were enough to rob him of self control. Once he had had an unmotivated attack of weeping. His record as a soldier was good save on one occasion when he had failed to get up in the morning. When interned he was pale, complained of headache, was alternately euphoric and anxious, and showed numerous peculiarities of behavior. He was first tested with ordinary association (Jung-Riklin) which was at least 93 per cent. internal. Great uniformity was shown, and the total results pointed strongly to epileptic association. Free association tests *per se* could throw no light on the amnesia and the patient was then hypnotized. Under hypnosis certain things were remembered but there were many gaps and posthypnotic suggestion failed completely. It seemed beyond doubt, by the character of the recollections, that during the twilight state patient had been in a delirium which by its content suggested an organic brain disease.

Book Reviews.

Diagnosis From Ocular Symptoms, By Matthias Lanckton Foster, M.D., F.A.C.S. Member of the American Ophthalmological Society; Ophthalmic Surgeon to the New Rochelle Hospital; First Lieutenant in the Medical Reserve Corps, United States Army. Price, $6 net. New York: Rebman Co. 1917.

This book is not really so bulky as it appears at first sight, being printed on light paper; the print is large and clear. Personally we regret the absence of illustrations. The book is one for students and practitioners and is well adapted to their requirements. So many important eye conditions are overlooked by the internist whose attention is elsewhere—a trigeminal neuralgia, for example, is in his mind rather than a possible glaucoma—that frequent reference to Foster's work cannot but be of great benefit to the practitioner. It is equivalent to having ever before one the lecture of a specialist adapted to the comprehension of the student. Like all teachers, Foster occasionally stresses subjects others might slur somewhat and vice versa. Thus in discussing occlusion of the central artery of the retina (p. 368) he merely mentions the "cherry red spot" which is the diagnostic point and should be emphasized to the general practitioner. But these are minor points and the book is, as a whole, so well considered that it must be regarded as a valuable addition to the practitioner's library. We predict an early second edition.

Diseases of Children; A Manual for Students and Practitioners, By George M. Tuttle, M.D., Clinical Professor of Pediatrics, Washington University Medical School; Consulting Physician, St. Louis Children's Hospital; Attending Physician, St. Luke's Hospital; Consulting Pediatrician, St. Louis Maternity Hospital, and Phelps G. Hurford, M. D. Pediatrician, St. Louis Lutheran Hospital, Assistant in Pediatrics, Washington University Medical School; Physician to Out-patients, Pediatric Clinic of Washington University; Associate Physician, St. Louis Hospital for Infectious Diseases. Third edition, thoroughly revised and enlarged. Illustrated with forty-seven engravings and three plates. Price, $3.50 net. Philadelphia and New York; Lea & Febriger, 1917.

This book professes to be for students and practitioners and fulfills this requirement admirably. It covers the entire ground of pediatrics in a concise, but complete manner. We have seen much larger works that were not so valuable to the general practitioner who has to dig for the essential information which in the present volume is served up, stripped of non-essentials. It is, in fact, the best book of its size dealing with pediatrics we have ever seen. A few minor faults must be noted, however. The arrangement might be criticized, thus, all gastrointestinal disorders might have been considered together, diarrhoea, for example, instead of being regarded as a symptom of several disorders, is treated first as a clinical entity and then there is unavoidable repetition in other parts of the book. In the section devoted to infant feeding—that *bête noir* of all who write on pediatrics—too much stress is put upon the mathematics of obtaining definite percentages and too little upon the interpretation of results. This book also advocates the use of limewater, a procedure which has been relegated to the scrapheap by most pediatrists. The book is a handy size and printing and binding are good. For some unknown reason, the first page of text is numbered 17.

Text Book of Ophthalmology. By Hofrat Ernest Fuchs, Professor of Ophthalmology in the University of Vienna. Authorized Translation from the Twelfth German Edition. Completely Revised and Reset with Numerous Additions Specially Supplied by the Author and Otherwise Much Enlarged by Alexander Duane, M.D., Surgeon Emeritus Knapp Memorial Hospital, New York. Fifth Edition. Price, $7.00. Philadelphia and London: J. B. Lippincott & Company, 1917.

The new edition of Fuchs forms a volume of 1067 pages. The work has been completely revised and greatly added to by the author and by his able colaborator, Dr. Duane. The many additions made and the resetting of the text brings the work thoroughly up to date and makes the subject matter much more easily accessible than was the case in former editions. Many illustrations have also been added. The work, as it now stands, is very comprehensive and is one of the best, if not the best, for the practicing ophthalmologist, in the English language.

Part I is devoted to a consideration of general physiology, general pathology and general therapeutics of the eye. Part II has to do with the examination of the eye. Part III with diseases of the eye. Part IV anomalies of refraction and accommodation and Part V with operations.

A work of this kind is of necessity the result of many years of labor and the degree of excellency now attained can only come through repeated and careful revisions and additions. The work needs no commendation farther than to say that the last edition is far superior to its very excellent predecessors.

Glaucoma. A Handbook for the General Practitioner. By Robert Henry Elliot, M.D., B.S. London, Sc. DD., F.R.C., Evg., etc., Lieut. Colonel, I.M.S. (retired). Late Superintendent of the Government Ophthalmic Hospital, Madras; Late Professor of Ophthalmology Medical College, Madras; and Late Fellow of the University of Madras; Honorary Fellow of the American Academy of Ophthalmology and Oti-Laryngology. Price, $1.50. New York: Paul B. Hoeber, 1917.

This volume of 60 pages is forcefully written by an author of very extensive experience who has made glaucoma a special study for many years. "The book is addressed to the busy practitioner in the hope (1) that it will put him on his guard so that he may not overlook cases of glaucoma when he meets them, (2) that it will teach him to make sure of his diagnosis in case of doubt and (3) that it will serve to indicate to him the latest lines along which the treatment of the disease is conducted today." Secondary, juvenile and congenital glaucoma in addition to simple and congestive glaucoma are considered; there are numerous illustrations in the text. The book is a very creditable production and is deserving of careful perusal.

Clinical and Laboratory Technic. By H. L. McNeil, A.B., M.D., Adjunct Professor of Medicine and Instructor in Physical Diagnosis, University of Texas Medical School, Galveston, Texas. Illustrated. Price, $1.00. St. Louis: C. V. Mosby Company, 1916.

In the author's own words the aim of this book is to present in as simple and practical a manner as possible the triad of history taking, physical diagnosis, and laboratory analysis, because it is through the application of these three diagnostic procedures, with an ability to weigh and judge the outcome, that the scientific practitioner of medicine today interprets, alleviates or cures those who come to him for the proper knowledge and assistance he must of necessity possess. It is therefore to be understood that this little work is not written for beginners, but for those who are already schooled in the principles and practice of medicine.

With a few exceptions all of the laboratory tests presented have been and are used as a routine measure in the medical clinics of the John Sealy Hospital. These exceptions are, of course, analyses of the gastric and duodenal contents, the chemical examinations of the stools, blood cultures, Widal's. With the exception, too, of the technique which is given for the examination of the fresh gastric contents and duodenal contents, and of the technique for the detection of the pancreatic ferments in the duodenal contents and stools, in suspected cases of the pancreas, nothing is offered which is not found in other books on the same subject; as the author further states, the only difference between this book and many others being that all theory is omitted from its pages and only strictly practical details are given. The tests are also given in the systematic way in which they should be carried out in private practice.

Aside from the clearness, briefness, and solidity of the subject matter presented, the manner of presentation should train those practitioners, who have a tendency to work in a slipshod, headless, albeit scientific manner, to think and establish correct, systematic habits in their daily routine examinations with their patients.

Stated Meeting, Held May 10, 1917.

Dr. Roger H. Dennett in the Chair.

The Aural Complications of the Exanthemata. — Dr. Henry Lounides Lynah read this paper. The percentage of acute suppurative otitis media in the exanthemata was governed by the degree of severity and the duration of the nasopharyngeal lesion at the outset of the disease. In diphtheria, even when the throat lesion was severe or the nasopharyngeal or glandular type, it was rather rare to meet with aural complications. The percentage of aural infections in this disease clinically varied from 2 to 4 per cent., the greatest number occurring in the intubated cases. A few years ago it was the custom to feed all the intubated cases by the gavage method; the percentage of otitic complications at that time was about four times as high as at the present time. Since these methods had been discontinued aural complications were almost unheard of. He had yet to see an adult with diphtheria develop a mastoid. In scarlet fever the percentage of aural infection was seldom below 10 per cent. and might even be as high as 30 per cent. The great majority of these complications in scarlet fever occurred early in the disease. The tonsils and adenoids were a constant source of infection and reinfection during convalescence and this accounted for aural complications occurring late in the disease. The early aural infections occurred in the postnasal and glandular type of scarlet fever in contrast to the small number of infections which occurred in the similar type of diphtheria. In measles the percentage of aural infections was usually from 10 to 12 per cent. The greatest percentage of infections occurred in the catarrhal and postcatarrhal stages and seldom later than the end of the second week. In a study of the cardinal symptoms of aural complications in the exanthemata taken collectively, it was not so much to the symptoms that were present, as to the absence of symptoms that he would direct attention. Pain was frequently masked at the onset and as a constant sign was rather unreliable. The temperature was invariably high at the onset in all severe types of scarlet fever and measles, and the otitic complications seemed to have no more influence on the temperature curve than the necrotic throat lesion or cervical glands. In many instances subperiosteal abscesses might develop with no rise in temperature, but it was not infrequent in scarlet fever and measles to find extensive destruction of the mastoid process and the temperature not be elevated about 99° F. The temperature curve, while usually an important symptom, was frequently subject to wide variations. The appearance of the drum membrane in the ordinary catarrhal type was little different from that seen in the ordinary infections. Marked retraction was far more frequent than bulging in the severe cases early in the disease, but when middle ear infection took place the membrane tympani presented a peculiar purplish gray color. Sagging of the posterior-superior wall of the canal was a fairly constant sign. The character and duration of the discharge and the appearance of the drum membrane as to sloughing and persisting sagging of the canal wall were the most reliable signs indicative of mastoid involvement. The preventive measures were the removal of the tonsils and adenoids. The polyvalent serum had apparently done good and was worthy of further trial. Nose and throat irrigations should not be blamed for the high percentage of aural complications; they might be a cause, but when carefully performed seemed to have little influence on the otitic complications. The treatment of these conditions was purely by surgical methods. Early and free incision of the drum membrane was indicated when there was the slightest sign of congestion and always preferable to spontaneous rupture. It had been his observations that had convinced him that early operation in mastoid disease was absolutely contraindicated in the case of many complications. He had been practising conservative measures in all of his many complicated cases and had had a very low mortality.

Dr. Henry Koplik asked Dr. Lynah if he had made use of an examination of the ocular fundi in cases in which both ears were involved and it was difficult to determine on which side there was sinus involvement. This examination was sometimes very useful, as one might find hyperemia and choked disc on the side that was involved. He supposed there would always be a strife between the otologist and the pediatrician with reference to operating on severe cases of otitis in babies; in these severe cases, whether they were primary or secondary to some one of the exanthemata, there must be some involvement of the mastoid and the only question seemed to be whether they should drain from in front or behind. These children usually got well after free and repeated incisions of the posterior wall and incision down to the bottom of the canal. The average otologist was satisfied with a small incision. In his hospital service free incisions were made and it was very seldom that they had to do a mastoid operation.

Dr. Henry Heiman said he wished to register his protest against the too frequent and promiscuous incision of red drums. He formerly permitted the incision of these ears by the consultant whenever he advised this procedure, and he used to have three or four mastoids a year. Now, when he did not allow the consultant to dictate in so many of his cases, he did not have more than one mastoid in ten or twelve years. There must be something radically wrong in doing a free and early incision; they had found that if they waited and managed their cases on common sense lines the children got well in most instances, excepting where there was intense pain and bulging. He had been ultra-conservative and had had no reason to regret it.

Dr. Lynah, in closing, said that in answer to Dr. Koplik's question as to whether the ocular fundi were examined, he might say that the fundi were examined in the case with the positive blood culture, but no papillitis was noted in either disc. It had been their experience that papillitis was a sign of sinus thrombosis, but no choked disc was present in the case recorded. Of course, some of the cases recovered after the free incision of the drum membrane and mastoid operation was not necessary, but in others frequent incisions were necessary and even then proper drainage was not established. It seemed to make little difference as to the size of the incisions or whether a posterior triangular cut was made; all of them had a tendency to close and leave only a pin point opening, causing damming back of the drainage and finally one had to do a mastoid operation. He did not believe, however, in doing a mastoid operation on every case that showed one or two symptoms, but was speaking of the cases that required many incisions to establish drainage. In these cases drainage was never established until mastoidectomy was performed. As to the early incisions of the slightly reddened drum membrane, it had been his experience that the slightest redness of the drum membrane called for immediate and free incision rather than allow spontaneous rupture. Dr. Lynah related the history of a patient seen in private practice in which the cause of infection was the Friedlander bacillus and in which he made the incision of the drum membrane on the two symptoms of constant irritability and inability to sleep; the conditions found made it evident that had this not been done the patient would have developed meningitis. In this instance the incision was fortunately made in time and the life of the patient saved.

Systematic Boarding Out versus Institutions for Infants.—Dr. Henry Dwight Chapin presented this paper in which he showed that the statistics covering the past three years, which had been compiled under the supervision of the State Board of Charities, demonstrated the high mortality of infants in institutions and compared these with the results obtained by the Speedwell Society, which for the past fifteen years had been boarding out infants at Morristown, N. J. The records of the Speedwell Society showed that for the past year there was a mortality of 16 per cent. among a class of marasmatic babies under six months, all of which would probably have died under institutional care. Dr. Chapin emphasized the importance of in-

dividual care and fresh air for these infants and described the details of the work, laying special emphasis on the importance of constant daily supervision of the babies by a trained nurse under direction of a physician. He also showed that financially the boarding out system was more economical than institutional care. (See MEDICAL RECORD, June 17, 1916, p. 1081.)

The Care of the City's Dependent Children.—Hon. J. A. KINGSBURY, Commissioner of Public Charities, said that they had inaugurated on March 1, 1917, a policy which would result in a more marked diminution of the infant death rate than had been seen in many years. In 1916, 16,000 infants died in New York City. They ordinarily committed eighty-seven babies a month without question; the mothers simply gave their babies up by surrender. The State Board of Charities required that the Commissioner of Charities should see that the dependent child got a chance to develop into a strong, normal man or woman, but the law also required that they investigate the circumstances of every proposed commitment to find out whether the child was a public charge, whether the parents had settled in the city, and whether they were able to support it. Some controversy grew out of the question whether these children were properly committed and they made an investigation into this. The investigation showed that in some of the institutions the children had vermin, were overworked and underfed. He said he could now report that the children were no longer overworked and underfed, that they were no longer sitting on backless benches and eating from coverless tables and walking lock-step. Since last October the children under eight years of age had been given to foster homes and not to institutions. About 4000 children had been placed in temporary homes. The number of children in institutions had been about 24,000; it was now about 20,000. If their present program could be continued, within four or five years they would have reduced the infant population of institutions to 10,000. Practically all normal children were going to be placed in normal homes. They were also planning an investigation of the children at present in institutions for the purpose of classifying them. Children whose parents had died of tuberculosis would be placed in open-air schools, the cripples would be put together, as would the blind, etc. There were 15,000 normal children in institutions that needed normal homes and there were about 15,000 mentally defective children that were a burden and constant source of trouble to their parents who should be in institutions and segregated. The nearer the baby could be kept to its mother's breast the better chance it had for life, health, and strength; if they did not leave the baby with its mother, its chance was gone. The death rate of New York was going down this summer, for which the milk stations, the Department of Health, and other agencies would take the credit, but it really would be because they were putting children in homes where they could receive a mother's care.

The Care of Sick Children in the Home.—MISS LILIAN D. WALD spoke of the Visiting Nurses' Service of the Henry Street Settlement and said that in 1916 their service had cared for 29,015 cases, 33 per cent. of which was referred to them by physicians. A very small percentage came from various agencies. Next to the largest percentage of their cases came from the Metropolitan Life Insurance Company. With regard to the possibility of education in the homes, it had been their experience that they almost never found these mothers unteachable, if they knew how to approach them, used their own terms in making explanations, and using their own utensils with which they were familiar. They were conducting an economical visiting hospital. Nearly 30,000 people had found it to their advantage to have a nurse accessible, and these were not alone the very poor, but people on small salaries. Their hospital extended from the Battery to Yonkers and they hoped to extend its services to Richmond and Queens. The records showed that they cared for 3,988 cases of pneumonia last year with a mortality of 8.6 per cent. Of this number, 70 per cent. were children under five years of age.

Report of Committee on "A Proper Basis for a Law to Prevent Overcrowding in Institutions and Hospitals for Children."—Dr. THOMAS S. SOUTHWORTH, Dr. WILLIAM L. STOWELL and Dr. PHILLIP VAN INGEN made this report, which was presented by Dr. Southworth. This committee was appointed by the Section on Pediatrics in response to a request from the Executive Secretary of the Public Health Committee of the New York Academy of Medicine to render an opinion as to what constituted a proper basis for a law to prevent overcrowding, which was prejudicial to the health of children, and as to the advisability of changing the present law. An examination of the present law seemed to show that it was designed to apply to dormitories or sleeping quarters of older children and that there was no evidence that the framers of the law had in mind its application to infants, whose nutrition and susceptibility to disease called for the best possible care and hygienic surroundings, differing in no essential respect from those obtaining in hospital wards. That hospitals were specifically exempted by the law strongly supported this view. It had, however, for many years been applied to such infant wards in institutions. While specifying 600 cubic feet as a minimum, the law gave any local board of health the power, in any ward where the opportunities for ventilation were judged sufficient, to reduce this allowance for each occupant of the ward to any degree which they approved. Under this clause the space required per inmate had been reduced in many institutions for infants to about 500 cubic feet and printed and written permits were issued which must be displayed in the wards. The Monthly Bulletin of the New York Board of Health, August, 1916, stated that anything below 500 cubic feet per person was insufficient for an office worker, who was obliged to remain indoors practically throughout the year. These adult workers had opportunities to get more fresh air during the non-working hours. Institutional infants throughout a considerable part of the year remained commonly in the same crib and ward practically continuously during the entire twenty-four hours, and their attendants helped to vitiate the air of the ward. Three main factors entered into the question of cubic space per infant in a ward: (a) Space to afford reasonably pure air for respiration; (b) space to allow sufficient separation of the cribs in order to minimize air-borne infections; (c) space to avoid the overcrowding which operated to reduce the individual care which could be given to each infant by a limited number of nurses and attendants. Metabolic requirements of the infant were relatively much greater than those of the adult and there was need of a proportionately greater amount of oxygen. The metabolic experiments of Vierordt and others made it clear that the respiratory needs were but a single factor. Equally important were the temperature, humidity, and barometric pressure, and motion of the air in determining the heat expenditure of the body. Experience had shown that while breast fed babies might do fairly well under conditions of overcrowding which were fatal to bottle fed babies, the artificially fed babies required a maximum of space in order to thrive. For respiratory purposes an adult needed 30 cubic feet per minute of fresh air. Modern hospitals for adults required 1,800 to 2,000 cubic feet, with more for infection cases. Inquiry showed that pediatrists generally felt that children should have 1,000 to 1,500 cubic feet available, and these amounts provided in the modern hospitals for infants. The present law referred to ventilation free and adequate as if it were the simplest matter in the world. Mechanical methods of ventilation were admittedly unreliable. It was absurd to base cubic space for infants, permitted by law, upon standards so low that to prevent their being injurious to the infants they just be supplemented by measures which were often notoriously absent or neglected in common practice, and which up to the present time there had been no adequate method or power for enforcing. When one considered the stress now laid by pediatrists upon the part played by ward infections in the morbidity and mortality of infants when gathered together in numbers, the present proximity of cribs permitted by the law was to be condemned. If every infant were allowed a minimum of 100 square feet of floor space, equivalent to 1,000 feet of cubic space or more, according to the height of the ceiling, this distance of six feet could be approximated. In view of the foregoing

the Committee further reported that the present sections of the State law should be repealed or superseded and new sections enacted, making separate provisions for institutions in whose dormitories older children above the run-about age spent their sleeping hours. Also separate provision should be made for all wards containing artificially fed infants under fifteen months of age, all such wards being considered as hospital wards, whether the infants therein be nominally admitted or rated as well or sick infants. The law should provide for the installation in all wards of devices for window ventilation which should be practicable at all seasons when the windows were closed and should provide for frequent inspections to observe and enforce their use. Six hundred cubic feet as a general basis for babies, sick or well, nursed or bottle-fed, was too small. Two feet separation of the beds was too small to reasonably minimize cross infections. Pediatrists were of the opinion that 1,000 to 1,500 cubic feet were needed. When the standard was based on cubic space alone the above should be required. Cubic space was not a complete standard. Ventliation was important.

Dr. MAURICE FISHBERG said that for years he had been interested in social medical work, and medical sociology had always held an interest. Miss Wald had obtained most remarkable results in caring for sick children in the poorer sections of the city, where the people were living in badly ventilated tenements, many of them vermin-ridden. The Visiting Nurses' Service had obtained most remarkable results in caring for sick children in the poorer sections of the city, where they were living in badly ventilated tenements. It was noteworthy that given 100 cases of pneumonia in infants and children cared for in the best modern hospitals at least 33 per cent. would die. When they compared this with the low mortality rate obtained by the special care given by these nurses in the homes of the children, they would feel convinced that such work would not only save New York, but it would save the world. They would also come to realize that proper ventilation was by no means the only factor in the proper care of sick children. Dr. Chapin had rendered a service to the country; he had been a true pioneer in this work, which was not appreciated to the extent it deserved. The outcome of the present war would be a great reduction of immigration; the people at home would be needed. The birth rate in the United States had declined almost to the extermination of the native stock. The immigrants had supplied the birth rate until now. In orphan asylums the children, compared with children in the tenements, were much inferior both physically and mentally. The Municipal Research Bureau of this city sent an anthropologist from Columbia University to investigate 1,000 children and they were found to be four years retarded in physical development in height and weight, as compared with poor children taken at random on the lower East Side. He had made careful examinations on children discharged from institutions and found that they were shy, and feared people, and probably had a mental development of about three to six years behind that of children who had developed normally. Dr. Chapin was doing a most remarkable work when he kept dependent children out of institutions. If one went by Miss Wald's figures, she should be more encouraged by the medical profession.

Dr. ALFRED F. HESS said that what they wished to bring out was that if they wished to compare these two systems, the institutional care of children and the boarding-out plan, they must compare them at the same level. It was not fair to take a composite list of figures from the worst institutions and compare them with the figures, for instance, of the Sage Foundation babies' experiment or with the results of the Speedwell Society's work. In going over the records of twelve or thirteen years of the Speedwell work, they found that there was a mortality of 33.3 per cent. in children under six months of age and of 13 per cent. between six and twelve months. During the last year the mortality had been 16 per cent. for the babies under six months of age. The cases had been very few in number, not more than fifty in a whole year, which was hardly an experiment that could be considered as applicable to New York City. There were only twenty-seven cases treated under one year. That was all very well, but could not be compared with the cases here in institutions. He did not know whether it would be applicable if they took 1,000 cases and boarded them out properly. Or, again, take the Sage Foundation, where there were only ten babies for each physician and yet giving a mortality of 46 per cent. That was not a fair comparison.

Dr. CHAPIN said that Dr. Hess failed to mention the cases of gonorrheal vaginitis, scarlet fever, and other infections contracted in institutions and these he would like to hear about. During the earlier years he had sent out all kinds of diarrheas and toxic conditions and there was not a single case of that kind that would not have died in an institution. He did not board out babies as some institutions did, giving them to some poor woman and then seeing them once a year. His mortality certainly compared very favorably with the 100 per cent. of this class in institutions. Boarding out should be systematized and properly managed. If one took marasmus babies and boarded them out and got a mortality of only 16 per cent. under six months, they were doing very well; also the morbidity was a thing of great importance. In over 1000 cases he had had only three cases of measles in five years and then the disease had not spread to others. They knew that measles was often followed by tuberculosis in feeble children. Dr. Hess confessed that they did have gonorrheal vaginitis in their institutions and yet they did not take in children having this infection. The child that had vaginitis at home did not spread the disease, but when they had this in institutions it was spread. That was just the crux of the whole situation.

Dr. HESS said that gonorrheal vaginitis was not a disease of institutions, but one that was found throughout the tenements. Such cases did not come from institutions, but from the homes. As a result of their rejections, the population of their institution was two-thirds boys and one-third girls. With regard to measles this disease was acquired at home as well as in the institutions.

Commissioner KINGSBURY said that in his remarks he was not referring to the boarding-out system *versus* institutional care, but he simply wished to emphasize the matter of providing means whereby children could be left with their mothers. It was true that the institutions to which they had referred did board out children and they were seen but once a year. That form of boarding out children was only jumping from the frying pan into the fire. He did not wish to see children boarded out unless they were given as intensive care and supervision as Dr. Chapin had described.

SECTION ON MEDICINE.

Stated Meeting, Held May 15, 1917.

DR. HARLOW BROOKS IN THE CHAIR.

The subject of the evening was "War and Medicine."

Introductory Remarks.—Colonel CHARLES RICHARDS, Department Surgeon, U. S. A., made this address. He stated that the people in general did not realize the very serious condition which confronted our country at the present time. The population of the United States did not realize the extent to which present conditions would influence our future. This lack of a full realization of the situation was due in part to our form of Government and in part due to the fact that we were isolated from foreign countries and our general policy had always been one of non-interference with foreign affairs. But now this had changed and we had become really a world power, and it behooved us to prepare for what was about to come to us most surely. So far as military affairs were concerned we were entirely unprepared. Our standing army was at its minimum limit. So far as medical officers were concerned the regular allowance was 0.7 per cent. of the enlisted troops. If the army was increased to 500,000 now there would be required 3500 medical officers and that would mean that there were needed 2000 not in the regular army. If an additional army of 500,000 was raised at the end of six months that meant a need of 3500 additional medical officers. Colonel Richards stated that the main thing

he wished to impress on his hearers was the necessity of every doctor in the country doing his share in this crisis. It made no difference what his age or his circumstances were, it was due the country that he should do his share. The younger medical men should go forward with the troops at the front. In order to do this they must be efficiently trained. Within a few weeks something like 1000 people would go to France to establish base hospitals. The condition in Europe was a very precarious one. Democracy was in danger; if we were going to maintain the spirit of Democracy we must see to it that all the younger men should come forward and volunteer their services and that the older men should stand ready to give their services at home in caring for the troops at home, caring for those sent back from the front, and in taking the places of younger men so that they might be free to go to the front. Every specialist would find a place where his talents could be used. The problem of placing each man in that place which he was best fitted to fill was the one that they now had to solve; he did not know just how this was to be done, but felt that the way would be found. Medical men were apt to think that because of their lack of military training they could be of little use, but he wished to disabuse them of this idea. Men with the mental training of those in the medical profession could soon acquire some knowledge of military sanitation and administration and other necessary requirements. The younger men could pick up the detail of the work quicker than the older ones. In closing, Dr. Richards said: "All I can say is to plead with you to do your share to maintain the spirit of liberty that exists in all of us if it is only brought out."

Tuberculosis and War.—Dr. MAURICE FISHBERG read this paper in which he pointed out that in histories of the epidemics during and after wars no mention had ever been made of tuberculosis as being excessively prevalent. Neither the soldiers, nor the non-combatants were reported as suffering or dying from tuberculosis in larger numbers than would be expected under peace conditions. This fact alone should lead us to expect no increase in the morbidity and mortality from tuberculosis during the present great war in Europe. Available evidence, published by those who, because of their exceptional opportunities for observation of soldiers at the front, were competent to express an opinion on the subject, showed clearly that there had been no change in the morbidity and mortality rates from this disease in England, France, Germany, Austria-Hungary, Russia and Italy. Dr. Fishberg brought together considerable statistical material in substantiation of this contention. He showed that the large number of consumptives was only absolute; when considered in relation to the large number of men engaged in the battlefield, the proportion was quite small. Even in France, where the number of soldiers discharged from service because of tuberculosis had been estimated at 150,000, this must not be considered an excessive number. Among 6,000,000 or more adult males, mostly between 20 and 35 years of age, in the army of France during the past three years, 150,000 constitute but 2.5 per cent., and this was rather low for peace time, especially for France, where the morbidity and mortality from this disease had been higher than in other civilized countries. He also quoted figures from William Osler's writings that in England there had not been observed an increase in the tuberculosis morbidity and mortality since the war began. It was Dr. Fishberg's opinion that in evaluating the fitness for military service examiners should not reject individuals because of a history of past attack of tuberculosis, or of having been patients in sanatoriums. His main reasons were that a substantial proportion of sanatorium patients had never been sick with phthisis; a larger proportion had been affected with the abortive form of the disease and had completely recovered, and many who had suffered from the chronic forms of the disease recovered to such an extent as to be considered completely cured and fit for any human task, including military service. Only symptoms of active disease, especially fever, tachycardia, dyspnea, emaciation, excessive cough and expectoration should be considered valid causes for rejection. He quoted experiences of military surgeons in the field, and in hospitals in Europe, to the effect that many soldiers who had suffered from tuberculosis before they entered the war had made brave and good soldiers, and had returned from the field healthier than when they enlisted for service. Nor had it been observed that active military duty was more liable to reactivate latent or dormant tuberculosis processes; many affected with quiescent disease had done well. It was extremely rare that gun shot wounds of the chest when the patients survive the injury, should develop tuberculosis, nor was it common that injuries to bones or joints inflicted during warfare should terminate in, or be infected with, tuberculosis. Dr. Fishberg stated that the problem of tuberculous infection of soldiers need not be considered seriously. Despite the large number of tuberculous soldiers in the European armies, those entitled to an opinion had not seen cases of tuberculous infection acquired while serving during the present war. His reasons were: Most adults had been infected with tubercle bacilli during childhood, and had thus been immunized against exogenic reinfection with the same virus, and they were just as safe in the army as in civil life. In nearly all tuberculous soldiers discovered in the European armies it was ascertained that they had already been affected with the disease before enlistment. Reactivation of old, dormant lesions occurred in civil life; it was doubtful whether it was more likely to occur in military life.

Medical Experience in South-Eastern Europe. — Dr. GEORGE BAEHR related the history of the expedition sent out from Mount Sinai Hospital in 1915 and which worked officially under the American Red Cross. He explained that their original plan had been to limit their work to Serbia, but after the invasion of that country they had gone to Bulgaria, Volhynia (Russia), and Galicia at the invitation of the Bulgarian and Austro-Hungarian governments. (See MEDICAL RECORD, Feb. 17. 1917, p. 300.) The military operations that had necessitated their various changes of location had brought them into contact with the ways in which medical affairs were conducted by the French, the British, the Austro-Hungarians, and the Germans. Their experience had therefore been very interesting and varied. They had had the opportunity of studying bacillary dysentery, amebic dysentery, and typhus fever, as well as other fevers. Of particular interest was an outbreak of typhoid fever among the New Zealand troops at Gallipoli, though these troops had been vaccinated against typhoid fever. The Canadian and Australian troops were equally exposed to the disease but did not contract it. There was probably a mistake made in the manufacture of the vaccines; at least it was quite evident that it did not confer an equal degree of immunization to that employed in vaccinating the other troops. Other diseases with which they came in contact were Malta fever, sand-fly fever, and relapsing fever. The Malta fever was not widespread, but they saw a few cases in which the diagnosis was made by the cultures and the agglutination tests. The sand-fly fever was very interesting. It began with high temperature, oftentimes a chill, flushed eyes and face, and headache. It could not be differentiated at first, but on the third day a crisis would occur and a rapid recovery would ensue. These patients practically always recovered and there were no sequellæ except occasionally neuritic pain which might persist for several weeks. This disease was widespread. Then there was relapsing fever which was one of the commonest diseases met with. At one time or another about 95 per cent. of the staff of the Lady Paget Hospital had it. Salvarsan in small doses was a very effective treatment. Sometimes a second dose was needed; that was when there was a secondary attack after an acute attack. Of typhoid fever they had seen only a little owing to the various methods of immunization. The American vaccine made by Dr. Castellani was largely employed. This was a tetravaccine made of typhoid, paratyphoid A and B, and cholera bacilli. No cholera was met in 1914 and 1915, excepting a few cases that occurred in outlying districts. In Russia there were a considerable number of typhoid fever cases among the vaccinated, but they usually ran a mild course. A point of significance in the diagnosis of typhoid fever was that in those who had been vaccinated against typhoid and who subsequently developed febrile

disease, the Widal became positive. An interesting point in the administration of medical affairs in the German and Austro-Hungarian armies was that the sanitary service was divorced from the rest of the medical service. There was a Sanitary Commission, practically an army board of health, whose function was the control of contagious diseases. Powers were lodged with the head of this department which made him particularly independent. He controlled twelve hospitals for contagious diseases and others for quarantine purposes. Other members of this sanitary commission were scattered through the country, and were responsible for the health of villages. These men were usually clinicians, and it was their duty if they found a case of smallpox or other contagious disease to see that it was sent to a contagious hospital, and that all who had come into contact with it were quarantined. There was no doubt that in the control of typhus fever this method had been of great value. In this connection it was well to emphasize the point that while in their endeavors to stimulate enlistment they had been calling for bacteriologists and surgeons, attention had not been sufficiently directed to the need for clinicians in the army. The clinician formed a very important part in the solution of the problems that an army anywhere would be called upon to face.

The Civilian Practitioner and His Relations to the Military Service.—Colonel W. S. TERRIBERY, Chief Surgeon, National Guard of New York, made this address, in which he said that as we had already been told, this country was facing a crisis the most serious since the Civil War and in many ways more serious. The first element of the people to realize this was the medical profession. In Great Britain and France the medical profession were used up; two and one-half years of war had demoralized them and broken them down and their need for help was urgent. This brought him to the main point and that was the great need of medical men at the present time. With a regular army of 250,000 and a conscripted army of 1,000,000 men there would be need of 8,500 medical officers and in addition there would be needed men to maintain 25 per cent. of the medical force of Great Britain and 50 per cent. of the medical force of France. This made the number of medical officers needed simply appalling. It should be remembered that this was the irreducible minimum of 0.7 per cent. of the army that was allowed for medical service. If we divided this number into one-half we would need something over 4,000 doctors at the present time. For the conscripted army there were as yet practically no medical men provided. Of the absolute need for these men there could be no doubt. Everyone in a position to know realized that the medical department was one of the most important, if not the most important, departments of an army, for upon its efficiency depended the economy of men. The military sanitary corps was the one part of the army that was conservative and not destructive. To make this part of the army effective meant that medical officers coming into the army must learn a new specialty, military hygiene. It was not a specialty that could be learned to any extent from books or from reading. The men who were conducting this sanitary work must not only continue to do the practical work, but must train the men coming into the service in this new specialty, and furthermore the majority of men coming into the service would be needed as sanitarians. Men in every specialty would be needed; the problem, as had been said, was to find where each man would be most serviceable. A way of organizing and coordinating their efforts so that this end might be attained was urgently needed. The need of medical men among the civil population would still remain. The general population must also be well cared for or they would become less willing to support the Government. Hence the physician who did his part in caring for the civil population was also rendering a service to his country. Another matter to be brought to mind was that there would be a vast number of men to be examined in the work of recruiting. In obtaining 150,000 recruits it was probable that double that number of men would have to be examined. This meant that the services of almost every doctor would be required. This work required also a special knack. Physical fitness did not necessarily mean absolute soundness in every particular. Sometimes those with certain subsidiary deviations from the standard were better fitted than others who showed no deviation from this standard. The permissible deviations from the standard had to be learned by the examiner. With reference to tuberculosis it might be said that hitherto this disease had not been a great factor in the army, there being not more than about five men per thousand who developed this disease in the army, yet every medical man in the army had seen these cases develop and when this occurred the victim was a source of infection to others, it was advisable to exclude those men who were reasonably sure to develop active tuberculosis. It required men specially qualified to tell them which men should be thrown out. Valuable men were sometimes thrown out on a suspicion of tuberculosis and others were thrown out for flat foot, varicose veins, etc. One had to be guided by the rule of reason, and that meant that the specialists in civil practice would have to tell them where to draw the line. This brought them again to the problem of coordinating their efforts so that everybody might give to his country the service that he was best fitted to give. The important point was that everybody should do "his bit" in this war. The men who were older or physically unfit for active service might do the hospital work of younger men and thus release them for active service. The active young men should learn military sanitation and go to the front, while the older men should be in the base hospitals on the lines of communication, and in the hospitals at home. It must be borne in mind that the medical profession was going to do its part; its members had never been "slackers."

Medical Experiences in the Balkans. — Dr. HARRY PLOTZ told of his experiences in the Balkans, confining himself more particularly to his experiences with typhus fever. He stated that when they arrived at Belgrade the large epidemic of 1915 was practically ended but typhus fever was endemic in Turkey and Bulgaria and was often confused with relapsing fever and typhoid fever. No one knew how the epidemic of 1915 started, but following the capture of 70,000 Austrians by the Serbs, these captives were huddled together in barracks and before it was recognized the epidemic of typhus had spread from one camp to another, like wildfire. They had two hospitals, the one at Belgrade and the Lady Paget Hospital at Vistent. At Belgrade where there were accommodations for 500 patients they had 2,000 and it was all the staff could do each day simply to go through the hospital and pick out the dead and bury them in trenches. It was estimated that 135,000 persons died during that epidemic. Forty of the seventy thousand Austrian prisoners died. Of 400 doctors 200 died. The American expedition arrived late and as the warm weather was coming on the epidemic was about over. It happened that they were then taken prisoners and taken into Russia and they got back just as the epidemic in Roumania was beginning. During the occupation of Bulgaria by the British and the French many deserters from the Bulgarian army and many of the peasants scattered back into the country through the villages, and after the French and British retired they were brought back, and it was found on examining them that they had come from villages where typhus had raged during the previous year. In that way the epidemic of 1915 started. The disease, however, was not as severe as it had been the previous year. In 1914 the mortality was calculated at 60 per cent.; in 1915 at 11 per cent. They had in all 10,000 cases in 1915. The most important factor in connection with typhus fever was the louse. The problem of preventing or controlling typhus fever was a problem of delousing the people. The German way of handling the problem was effective. If a case of typhus was discovered in a village the patient was isolated and deloused and the village was quarantined for three weeks. At the front their rule was that every man should spend one hour every day delousing himself. They also had another method. They had a small three-room house where men went to be deloused. A man undressed in one room, sent his clothes into the second room to be steamed, and went into the third room where his hair was cut and he was bathed. The only articles of clothing not disinfected were the shoes. Thousands along the frontiers were deloused in this way. Before leaving for home their part" went to

Salonica and while there learned that a Turkish doctor conceived the idea that he might vaccinate against typhus by using the blood of typhus patients. He made 200 of these inoculations and got a mortality of 59 per cent. In their experience with vaccination against typhus they had vaccinated physicians, nurses, orderlies, and others coming in contact with typhus fever. There were of these about 10,000 in all; among these vaccinated individuals only six contracted the disease. After vaccination was instituted they had had no louse infections.

Dr. N. S. JARVIS said he was particularly impressed by the earnest, honest, and logical remarks of Colonel Richards. He had been forty years in the army; had been all over the world, and there was no doubt but that he was right when he spoke of the danger that confronted our country. Dr. Jarvis spoke of his experience at the headquarters of the Royal Army Medical Corps in London and of the members of that body as being the finest specimens of medical men he had ever met. Yet if reports were true, 75 per cent. of those men had suffered casualties and been put out of service. He related the experience of one young Australian doctor who was the only one left in a British hospital to care for 1,500 wounded men. In referring to Dr. Fishberg's paper Dr. Jarvis stated that tuberculosis in the regular army was a different problem from what it was in a conscripted army. They took much more care in examining men for the regular army than for a conscripted army. He thought it important that they should eliminate men who might possibly be tuberculous. Dr. Terribery had spoken of making the assignments of medical men according to their special fitness for certain lines of work. The great need of the army at the present time was not so much for specialists as for general practitioners.

Dr. LOUIS LIVINGSTON SEAMAN said he supposed the discussion was to be on food. There was one point he wished to bring out. At the time of the Russian-Japanese war, during the siege of Port Arthur, it was interesting to recall that the Russian army, on an animal diet, had at one time 19,000 cases of scurvy while at the same time the Japanese army was suffering from the diametrically opposite disease, beriberi, as a result of a rice diet. In other respects the conditions of these armies were similar. This furnished a marvelous example of the result of nutrition on an army. There were two foods the practical value of which should be emphasized in considering the problem of nutrition as it affected an army. These were smoked beef, which, with its considerable amount of gristle, was very nutritious and would stand any climate, and the other was rice, which was one of the cheapest and best of foods. Dr. Jarvis's remarks about the general practitioner should be emphasized. The general practitioner was needed in the army more than anywhere else. The specialist was of course of great service in the hospitals, but on the front lines the general practitioner was the man for the place.

Dr. L. T. LEWALD stated that he had had experience in examining recruits. Seven years ago the acting Surgeon General had brought out the fact that one-third of the cases of tuberculosis occurred in the first year after enlistment, and it was frequently impossible at the time of examination to detect latent infection. Being interested in the establishment of an *x*-ray department at Columbus, Dr. LeWald said he had asked permission to examine all the recruits by the *x*-ray. He had made this same request of Dr. Biggs about a week ago in connection with the examination of State troops. Dr. Biggs had undertaken to allow him to try this method out with the State troops. If they got the proof that the latent infections could be detected by the *x*-ray they would have made a great step forward in excluding such men, as it would save the country a great deal of money that would otherwise have to be expended in the care of tuberculous soldiers and in pensions. Experience in the detection of latent infections by means of the Roentgen rays in civil practice left no doubt in the speaker's mind as to the great value of this procedure.

Colonel RICHARDS closed with a further plea for enlistment on the part of all medical men, but especially the younger men. He urged the older men to exert every effort to appeal to the younger ones to offer their services in this time of need.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE MODERN MILK PROBLEM—IN SANITATION, ECONOMICS, AND AGRICULTURE. By J. SCOTT MACNUTT. 258 pages. Illustrated. Published by The Macmillan Co., New York. Price, $2 net.

NERVOUS AND MENTAL DISEASE MONOGRAPH SERIES No. 20. VAGOTONIA, A CLINICAL STUDY IN VEGETATIVE NEUROLOGY. By DR. HANS EPPINGER and DR. LEO HESS of Vienna. Second revised and corrected edition. Published by Nervous & Mental Disease Publishing Co., New York. Price, $1. 93 pages. Illustrated.

HANDBOOK OF GYNECOLOGY. For Students and Practitioners. By HENRY FOSTER LEWIS, A.B., M.D., and ALFRED DE ROULET, B.Sc., M.S., M.D. With 177 illustrations and 452 pages. Published by C. V. Mosby Co., St. Louis, Mo. 1917.

SHELL SHOCK AND ITS LESSONS. By G. ELLIOT SMITH, M.A., M.D., F.R.C.P., F.R.S., and T. H. PEAR, B.Sc. 135 pages. Published by Longmans, Green & Co., New York. Price, $1 net.

THE SURGICAL CLINICS OF CHICAGO. June, 1917. Vol. I, No. 3, with 70 illustrations. 679 pages. Published by W. B. Saunders Co., Philadelphia and London. Published bi-monthly. (Six numbers to a year.) Price per year, $10.

SCIENCE AND LEARNING IN FRANCE. With a Survey of Opportunities for American Students in French Universities. An Appreciation by American Scholars. 453 pages. Illustrated. Publshed by The Society for American Fellowships in French Universities. 1917. Printed by R. R. Donnelley & Sons Co., Chicago, Ill.

THE PRACTICAL MEDICINE SERIES. Comprising ten volumes on the Year's Progress in Medicine and Surgery. Under the general editorial charge of CHARLES L. MIX, A.M., M.D. Vol. III. THE EYE, EAR, NOSE AND THROAT. Edited by Casey A. Wood, C.M., M.D., D.C.L., Albert H. Andrews, M.D., and George E. Shambaugh, M.D. Series 1917. 372 pages. Illustrated. Published by the Year Book Publishers, Chicago, Ill.

A TEXT-BOOK OF FIRST AID AND EMERGENCY TREATMENT. By A. C. BURNHAM, M.D. 307 pages and 160 engravings and 2 plates. Published by Lea & Febiger, Philadelphia and New York. 1917. Price, $2 net.

UNIVERSITY OF IOWA MONOGRAPHS. STUDIES IN MEDICINE. Vol. I, No. 10. First Series No. 1, September, 1917. Collected Studies and Reports. Published by the University. Issued monthly throughout the year. Price, 40 cents.

THE ELEMENTS OF THE SCIENCE OF NUTRITION. Third revised edition, enlarged. By GRAHAM LUSK, Ph.D., Sc.D., F.R.S. Octavo of 641 pages. Illustrated. Price, cloth, $4.50 net. Published by W. B. Saunders Co., Philadelphia and London.

FOOD PREPAREDNESS FOR THE UNITED STATES. By CHARLES O'BRIEN. 118 pages. Published by Little, Brown & Co., Boston, Mass. 1917.

CONGENITAL WORD-BLINDNESS. By JAMES HINSHELWOOD, M.A., M.D., F.R.C.P.S. Glasgow. 112 pages. Illustrated. Price, 4 shillings. Published by H. K. Lewis & Co., Ltd., London. 1917.

DANGERS IN NECK WEAR. By WALTER G. WALFORD, M.D. 171 pages. Price, 4 shillings net. Published by H. K. Lewis & Co., Ltd., London. 1917.

PHYSICAL EXERCISES FOR INVALIDS AND CONVALESCENTS. By EDWARD H. OCHSNER, B.S., M.D., F.A.C.S. 54 pages. Illustrated. Published by C. V. Mosby Co., St. Louis, Mo. 1917. Price, 75 cents.

ROENTGEN TECHNIC (DIAGNOSTIC). By NORMAN C. PRINCE, M.D. With 71 original illustrations and 140 pages. Published by C. V. Mosby Co., St. Louis, Mo. 1917. Price, $2.

CORNELL UNIVERSITY MEDICAL BULLETIN. Vol. VI. April, 1917. No. 4. Studies from the Department of Surgery, including Urology, Gynecology, Laryngology and Ophthalmology. Published by Cornell University, New York.

A CONSIDERATION OF THE MERITS OF MEDICAL AND OF SURGICAL TREATMENT RESPECTIVELY IN PEPTIC ULCER.*

BY J. N. HALL, M.D.,

DENVER, COLORADO.

UNFORTUNATELY, physicians, like other men, too frequently tend to see one side of the shield only, and this tendency is perhaps as conspicuous in the decision regarding the method of treatment of peptic ulcer as in any other medical problem.

I should say at once that in my opinion there are definite and positive advantages and disadvantages pertaining to medical and to surgical treatment in various cases, and the course to be followed in any given case should be decided upon only after careful consideration of these factors.

Let us consider first the various types of ulcer, as viewed from a therapeutic standpoint, especially as to the possibility of cure by either mode of treatment. Nearly all clinicians would agree that an acute ulcer with little infiltration about its base may be expected to heal if it can be placed at relative rest, and freed from the corrosive action of an oftentimes overstrong gastric juice, and so maintained for a period of several weeks. Freedom from serious cicatricial contraction and from notable adhesions may be expected in such cases, so that, practically speaking, a complete restitution is attainable.

At the opposite extreme we may place the chronic ulcers with thickened base, oftentimes with extensive adhesions, and in the more serious cases with such chronic perforative processes as involve even excavation into the liver, or penetration of a portion of this organ or of the pancreas for example, into the cavity of the stomach through the large perforative opening, with, naturally, the most extensive and firm adhesions roundabout. Only a hopeless optimist could look for favorable results in these cases from medical treatment, for even with the best of surgery the outlook is none too favorable.

Between these two types we may place the majority of ulcers coming under the observation of the internist. The milder ones, with history of a short course in many cases, with no notable thickening, adhesions, or deformity of the canal (when these features can fortunately be determined), are certainly "medical ulcers" at the start, and many of them may be either cured, so far as we may determine this point clinically, or at least rendered free from symptoms by medical treatment. Those not faring so well may yet be subjected to exploration.

In general, ulcers showing the roentgenological signs of a protected perforation present such extensive adhesions and such crippling of the motor functions of the stomach that I have commonly assigned them at once to the surgeon.

In case of ulcer at or near the pylorus, of long standing and with marked food retention, Sippy claims entire cure in many cases by medical treatment. Provided the cicatricial contraction be not extreme, and that adhesions be trivial, we may grant this claim in many cases. There should be, in my opinion, no objection to a trial of medical treatment, but the improvement should be fairly prompt and decisive, as, fortunately, it generally is. The dangers of permanent pyloric blocking must not be overlooked, nor the chance of later hourglass stomach, nor the more tragic development of malignancy, which we so often find in these cases.

I think much more latitude is to be allowed in the use of medical treatment, in case of gastric ulcer, than in that of the duodenal type. The results of medical treatment in the latter, in my experience, have been much less certain, and the dangers of hemorrhage and of perforation much more to be feared. On the other hand, the lessened likelihood of cancer is to be given due weight in the decision.

To some extent the social status of the patient may influence us. If the subject must work daily for a living, the need of an attempt to secure a prompt and complete cure may decide us in favor of surgical intervention, while those who can afford to spend most of their time and much of their energy in nursing a diseased stomach may at least postpone such a course.

In general, we may mention as *advantages of medical treatment:*

1. Avoidance of immediate operative and anesthetic dangers. As in many other problems of life, certain individuals prefer to take years of lesser risk than hours of greater hazard. In no patients do we see better illustrations of this tendency than in those with peptic ulcer.

2. Avoidance of danger of occurrence of "vicious circle," later jejunal ulcer, postoperative adhesions, ventral hernia, etc.

3. In many cases, an advantage of medical treatment lies in the fact that work may often be continued at least in part during the medication.

4. Avoidance of the postoperative pain and abdominal distress appeals to many sensitive patients with peculiar force in favor of the medical treatment.

*President's address at eighteenth annual meeting of the American Therapeutic Society, held in New York, June 1 and 2, 1917.

Next, we may speak of the *advantages of surgical treatment:*

1. We should place first the overwhelming advantage of knowing precisely what we are treating. This factor should not be estimated too lightly by the therapeutic enthusiast, for all who have seen many of these cases upon the operating table can recall instances of supposed ulcer in which no ulcer existed, but in which the symptoms were due to chronic appendicitis, to gallstones, to adhesions about the gallbladder, to Treitz's hernia, to kinking of the duodenum because of anatomical aberrations, to adhesion of the gastric wall to the abdominal parietes at the site of a long-healed ulcer, etc. I think it is within the bounds of prudence to state that, in a very material proportion of the cases of ulcer and supposed ulcer coming to operation, even when they have been in the hands of the most eminent men of the profession, such failures of exact diagnosis are discovered and always will be discovered, since they are oftentimes wholly unavoidable even with the most intelligent use of all our present means of diagnosis. In other words, we may often determine very definitely that a lesion of some type exists, interfering seriously with gastric function, but the exact character of the lesion may not be susceptible of diagnosis. In this connection I quote from a previous paper:

"There are certain unusual conditions within the abdomen incapable of preoperative diagnosis, so far as I know, which may simulate ulcer so closely that years of medical treatment are submitted to in certain instances. Thus I have encountered pinching of the pylorus and duodenum in Treitz's hernia, as mentioned above; compression of the duodenum by the superior mesenteric vessels, with dilatation of its proximal portion; kinking of the viscus by adhesions about the gallbladder and pressure on it by gallstone, and distortion from various causes, bringing about partial obstruction. In some of these cases the diagnosis of ulcer seemed to rest on a solid foundation, since pain, hyperacidity, vomiting, hematemesis, dilatation of the stomach, rigidity and tenderness were present, but medical treatment was of little or no avail in any."

I have records of three cases, all treated for a time as ulcer, and in my opinion extremely difficult to differentiate from this condition. Yet all three were due to congenital anomaly in the position of the duodenum, and all were cured promptly by operation. It is a great advantage of surgical exploration that such a condition may be recognized and efficiently treated, while diagnosis is probably impossible by the usual clinical and roentgenological methods. Without giving the case histories, it will suffice to say that two of the patients had had the appendix removed without relief. All had the persistent sour stomach so commonly noted in ulcer. Two had daily and the third occasional vomiting. Hematemesis had occurred in one, and all three had long been confined to bed. Food relief was noted in one, and in one the stomach was much dilated. In all three marked tenderness and moderate rigidity were present at the epigastrium, and in all three a fairly high gastric acidity was found. In two of the cases complete relief was given by correction of the angulation of the duodenum caused by its anomalous position, and in the third by gastroenterostomy.

Because of the infrequent recognition of these cases I think it well to offer in detail the anatomical findings as given me in two instances by Dr. Leonard Freeman, and in the third by Dr. C. E. Tennant:

Case I.—"The duodenum ran directly downward, beneath the transverse mesocolon; then turning to the left it passed under the superior mesenteric vessels, well below the mesocolon, and appeared upon the left aspect of the mesentery of the small bowel. A strong band of connective tissue from the mesentery dragged a loop of the first portion of the jejunum upward to a point just above the place of emergence of the duodenum, in such a manner as to sharply kink the bowel. Above this kink the duodenum was dilated, as was also the stomach to a moderate degree. The pyloric opening was unusually large."

Case II.—"The condition represented a well-marked congenital anomaly. The duodenum did not, as it normally should, pass above the colon and beneath the stomach and emerge into the free peritoneal cavity through the mesentery of the transverse colon to the left of the spinal column. Instead of this it ran directly downward and through the colonic mesentery to the right of the spine. It then turned squarely to the left, crossed the vertebræ beneath the superior mesenteric vessels, and was looped up by firm adhesions (Treitz's ligament) to the point where it normally should have emerged; thus kinking it acutely, like a rubber tube hung over a nail, and producing a partial obstruction which gave rise to stasis and to marked proximal dilatation."

Case III.—"The stomach was of normal size and position and there were no scars about the pylorus. The duodenum, however, was quite as large as the transverse colon, and the terminal portion did not make its exit through the fossa duodenojejunalis. After considerable search the jejunum was found lying directly over and to the right of the vertebral bodies and its anatomical relation to the superior mesenteric vessels much the same as when the ascending portion of the duodenum is at the fossa duodenojejunalis on the left side of the vertebral bodies. There seemed to be no undue constriction at the ligament of Treitz, which was transposed to the right side of the spine, but crossing the bodies of the vertebræ were the mesenteric vessels directly over the transverse portion of the duodenum. Assuming that this transposition of the terminal third of the duodenum was responsible for the dilatation of the duodenum and the persistent vomiting, a gastrojejunostomy was made."

In another case, which had recently been subjected to a prolonged course of antisyphilitic treatment by a genito-urinary surgeon, the supposed ulcer symptoms were found to be due to a gumma of the liver, with extensive adhesions at the exact site of the pain and tenderness.

2. The chance of finding incipient and curable cancer of the stomach by exploration when the diagnosis of ulcer is apparently well established, should not be forgotten. In 6.4 per cent. of my first 93 cases of ulcer coming to operation, reported in 1911, cancer was demonstrated. Enough cures may be obtained in these cases by radical surgical procedure wholly to offset perhaps the usual mortality of operative intervention.

3. Even if the diagnosis of ulcer has been correctly made, there are many chances that a complication, as, for example, gallbladder disease, chronic appendicitis, Lane's kink, etc., may exist. Such complication is discoverable upon operation only, in many cases. I certainly think we are justified in taking the position that no medical treatment of gastric ulcer is justifiable in the average case if a definitely established chronic appendicitis is demonstrable. The ulcer may heal, but the same

pyloric spasm and hyperacidity which resulted from the appendical lesion, and which presumably caused the first ulcer, will probably cause a second one when the patient returns to his ordinary occupation and diet. The same reasoning should apply in case of many other complicating affections.

In one case a diagnosis was made of a previous ulcer, presumably healed, and of a new one at the pylorus. The scar of the former was found several inches from the pylorus, but the later symptoms were due to the intermittent pinching of the pylorus and duodenum in a Treitz's hernia, this being severe enough to cause hematemesis on several occasions. I do not think the differentiation from ulcer was possible, yet medical treatment would obviously have been futile.

4. The avoidance of many serious complications of ulcer should be credited upon the surgical side:

First, we should mention cancer, while less serious are permanent pyloric stenosis, extensive adhesions, gallbladder and pancreatic disease, hourglass stomach, perforation, hemorrhage, subphrenic abscess, and a whole train of complications which are worse than the original disease.

The danger of perforation is not to be disregarded. In my first 116 operated cases, 4 gastric and 4 duodenal ulcers perforated acutely. There were many instances of chronic perforation, so often indistinguishable from simple adhesions that the exact number cannot be stated.

The frequency and gravity of hourglass stomach from chronic ulcer must not be underestimated. This complication was present in 5 of the 116 cases above quoted, the stomach being trilocular in one instance.

5. Operation often enables us to remedy some annoying trouble which, in case of a so-called medical cure, will persist and render the patient a semi-invalid. As an example I will mention the small omental hernia so frequently found associated with peptic ulcer, and so often overlooked. It not infrequently causes as much distress as the ulcer, and is probably to some extent a causative factor in some cases. Adhesions to the anterior abdominal wall often occur, and after ulcer is healed still cause much distress.

6. By operation we occasionally preserve the patient from disaster by the avoidance of perforation, which we find imminent when the abdomen is opened. I have several times seen the peritoneal surface over the ulcer already covered with flakes of lymph. The difference between the light mortality of simple gastroenterostomy in such cases with repair of the ulcer and that after perforation has occurred, is to be considered.

7. In lingering cases the advantage of the decisiveness of surgical procedure contrasted with the long-drawn-out course of medical treatment is to be properly estimated.

The *disadvantages of medical treatment* may be mentioned as follows:

1. Uncertainty of diagnosis, as already mentioned. Let no one underestimate the danger of incorrect or incomplete diagnosis in these cases, no matter how skillful the attendant. One of Leube's supposed ulcers recovered promptly after 25 years of suffering when his appendix was removed, under my care, and the stomach was found entirely normal. I have seen a score of more or less similar cases.

2. Frequent complete failure of medical treatment.

3. Likelihood of relapse. Probably more cases relapse than remain well, if they return to the usual habits of life. This certainly does not hold in cases well treated surgically, so far as my observation goes.

4. Danger of hemorrhage and perforation. We may hope to dismiss these dangers, after operation, in nearly all cases.

5. Fear of development of the invalid habit, of chronic nervous prostration, chronic nephritis, arteriosclerosis, generally lowered resistance, with tendency to the development of tuberculosis or other chronic disease. The danger of the morphine habit is appreciable.

6. Under medical treatment we have the constant fear that malignant disease may develop. The presence of a high gastric acidity is not to be taken as evidence that cancer does not already exist, as I have learned to my sorrow.

7. The complications heretofore mentioned, and embolism, thrombosis, parotitis, phlebitis, etc., are too frequently encountered under medical treatment. We may repeat here that nearly all the mortality in peptic ulcer comes in some way from some complication. Obstruction by the ulcer, or by adhesions, of the biliary and pancreatic ducts is a serious possibility.

8. There are, unfortunately, many instances of subphrenic abscess, empyema, pyopneumothorax, septic pericarditis, mediastinitis, etc., which result as late complications of slowly perforating ulcers, their origin often wholly unrecognized.

Disadvantages of surgical treatment:

1. Danger of operation and of anesthetic. In good hands the mortality of perhaps one to three per cent., considering the seriousness of the disease under treatment, is to be regarded as justifiable.

2. Subsequent development of adhesions, vicious circle, jejunal ulcer, etc. These dangers are much lessened under modern surgical measures.

Gastrojejunal ulcers are generally conceded to be surgical, since they are so commonly dependent upon the use at the performance of the gastroenterostomy of a non-absorbable suture material which fails to come away. The less frequent jejunal ulcers are more amenable to medical treatment.

We should, then, weigh carefully the matter of the certainty of the diagnosis, the probability of relief by medical treatment, or of complete cure in favorable cases, the chances of relapse, the favorable or unfavorable physical condition of the patient, the danger of cancer, the possibility of relieving some complicating trouble by operation, the favorable or unfavorable occupation and surroundings of the patient, and, to some extent, the patient's desires. There should be no bias in the medical mind in favor of one line of treatment or another, excepting as it is based upon all of the above considerations.

METROPOLITAN BUILDING.

Repopulation of France.—Tayle insists that every Frenchman between thirty and fifty must have at least three children or be taxed to raise the children of others in the same social class to balance the deficit. Such a tax would be known as *l'impôt de génération.*—*Le Progrès Médical.*

AN HYPOTHESIS REGARDING THE PHYSICO-CHEMICAL NATURE OF CANCER.

By EDWARD PERCY ROBINSON, M.D.,

NEW YORK.

A PAPER entitled, "Biopsy and Cancer—A Review," by Dr. William Seaman Bainbridge, in the MEDICAL RECORD of April 23, 1917, suggests the timeliness of boldly questioning the efficacy of surgery in the treatment of carcinoma. Good reason exists for believing that in this particular field the surgeon, having been weighed in the balance and found wanting, should stand aside to give the hitherto discredited physician another chance to propose measures of relief.

The clinical history of cancerous growth in general may be summarized as follows: A hyperemia of any part of the body is set up either by an injury, toxic products from bacteria or from chemical substances. The hyperemia is followed by inflammation, this sets into action the processes of proliferation. Proliferation and growth continue up to a certain point governed by the condition of the plasma, after a certain time the process of cell division becomes disturbed and irregular in its nuclear division, the cytoplasm no longer dividing with the nucleus. This condition incites in the cytoplasm its property of making new chemical substances, which prevent further growth of the new species of cell and at the same time serves to cause necrosis.

All organs physiologically active in proliferation, and those abundantly vascularized, particularly the digestive organs, are most liable to cancer degeneration.

The frequency with which the generative organs of the female are afflicted with cancer cannot be due to mere chance, but must depend upon some existing factor. It is a remarkable fact that the breasts and the uterus seem to be the sites by preference for cancerous involvement, while the corresponding organs of the male are rarely thus affected. The reason for this may be outlined as follows: The female being a reproductive animal, it is reasonable to assume that the cells of her body, and particularly those of the productive organs, are endowed with greater power of proliferation than are those of the male. This function of cell proliferation would naturally exhibit greater activity in the uterus and the mammary glands than in other organs of the body. From the period of menstruation up to the time of the menopause, and perhaps some time after that, the cells of these organs undergo changes every twenty-eight days. The uterus becomes engorged and proliferation of the endometrium and of the body is proportionately active. The mammary glands show sympathetic changes and are more or less tender. If active proliferation is not actually present there is some hyperplasia of the cellular tissue, which subsequently resolves as soon as the period of menstruation terminates.

The breasts are particularly exposed to injury or irritation, produced by blows or even by pressure or friction from the clothing. The uterus, likewise, may suffer irritation from a lacerated cervix, or by absorption of toxic products from the rectum.

Improper elimination of effete products of the body by their toxic action on tissues must undoubtedly produce irritation followed by hyperemia, and if this condition persists a passive inflammation ensues. Starting from this condition it can be readily seen how proliferation might be excessively stimulated and the gradual formation of a circumscribed tumor developed. The frequency with which constipation is observed to accompany tumors and cancers of the uterus arouses suspicion that this association is not accidental, and tends to lend weight to the inference that cancer is a constitutional disease and not a simple local affection.

More reason for suspecting that the cause of cancer may be found in the constitution of the plasma is shown by the frequency with which organs having an abundant blood supply are affected. For example, the statistics compiled by the Department of Health of New York City show that cancer has increased remarkably in the past five years, those organs highly vascularized heading the list. The stomach and the liver show an increase from 31.4 to 33.8 per cent., the female generative organs from 12.3 to 13.3 per cent., the peritoneum and intestines from 11.6 to 13.3 per cent., the breasts from 7.7 to 8.5 per cent., while the skin is proportionately low, being only 1.3 to 1.7 per cent. The combination then of a large blood supply, active metabolism and physiological cell proliferation would seem to be predisposing causes to cancer.

Tumors are composed of the same types of cells as those normally existing in the body, and are derived from the latter by a proliferation of pre-existing cells. The cells of malignant tumors do not possess a characteristic structure or appearance, and there is nothing pathognomonic in the appearance of single cells. To determine the nature of a tumor, particularly cancer, it is necessary to consider the general structure, the gross appearance, and the clinical history in order to arrive at a definite opinion, and microscopic examination aids the diagnosis best when the tissue to be examined is taken from peripheral portions of the tumor.

No appreciable advantage is gained by a knowledge of the particular type of cell tissue which has assumed the character of a tumor, the existence of metaplasia is often recognized, nor can a degree of malignancy be determined by the character of the cells or their types. Bainbridge in his article in the MEDICAL RECORD, April 28, 1917, quotes Bloodgood as saying, "I have submitted over sixty borderline cases to a number of pathologists, and have found that in not a single one has there been a uniform agreement as to whether the lesion was benign or malignant." A tumor at its inception is not primarily a cancer and may never become one. Tumors are classified as benign and malignant; and it is known that any benign tumor may become malignant. It can be reasonably asked what brings about this virulence, a state of being capable of remissions and exacerbations and even spontaneous disappearance? It is hardly conceivable that the cells of the tumor are by themselves capable of this whimsical behavior, but must depend on the influence of some other agent for the change they acquire, and the only logical place that this can be looked for is in the chemical constitution of the plasma. For it must be admitted that a cell cannot act independently of the plasma in which it lives.

It has not infrequently happened, after an operation for the removal of a benign tumor, that malig-

nancy has developed in adjacent cells not included in the extirpation of the mass. From this it would seem that the traumatism inflicted upon the tissues by the operation had stimulated the growth of the cells lying dormant yet malignant. This transition may be brought about in the cells through their inherent property of proliferation as the first step toward repair in healing the wound, and the attempt at repair may have occurred at the same time that the cells were passing from the stage of benignancy into that of malignancy, with the result that their mode of division was interfered with and a depraved type of cell resulted. At what stage of mitosis this change occurs is merely conjectural and immaterial, but it is evident that the cells are beginning to lose their property of specialization.

Prof. F. H. Pike makes the following statement: "A single organism can grow and develop only up to a certain point, limited by its degree of specialization. That further progress may be made, the individual life must cease and give place to a successor."

Is it unreasonable to suppose that a tumor cell is one in which its degree of specialization has been interfered with and is incapable of further progress? If its method of division is not normally adhered to, it may be incapable of proliferating a daughter cell with parental characteristics, and in all probability will then take on the characteristics of a vegetative type returning to a primitive form and liquifying.

The property, inherent in the cytoplasm of the cell, of making new chemical substances, makes it quite probable that all growth is controlled by the cell and not by the plasma, as some have thought. As stated by Delafield and Prudden, "Different parts of the cell have special functions to perform. Thus, the nucleus presides over the constructive metabolism or assimilative process of the cell and furnishes the physical basis upon which the transmission of hereditary characters depends. The cytoplasm of the body, on the other hand, is concerned in those phases of metabolism which result in the liberation of energy in movements of various kinds and in the formation of new chemical substances."

Were it not for the controlling influence of the cell upon development, animals would grow into enormous shapes, vegetation would smother the earth, and the tops of trees would reach beyond the clouds.

Admitting that the cell possesses the property of controlling growth, it can be understood why some tumors, after having reached a certain size, cease to grow, and it must be assumed that a change has come about in the chemical constitution of the plasma, for unless this has happened the cytoplasm could not consistently manufacture new chemical substances.

During the thirty years in which cancer has been under investigation much has been learned regarding the things which do not cause it, but the direct etiology remains a mystery. The suspicion that the disease was produced by bacteria or parasites has been shown to be unfounded, and the belief that an injury preceded the development of cancer has not been conclusively proven, although traumatism is most certainly not an inert factor. So far the field of investigation has been well gone over and seemingly every corner has received attention, with perhaps the exception of the blood, which is indeed the most important source from which nearly all pathological conditions arise.

If it is asked, "What is the difference in the chemical composition of the plasma of a normal human being and that of one afflicted with cancer?" the question remains unanswered.

It has been suggested that from the chromosomes and their abnormalities may be derived an intelligible theory of the origin of tumors. The old view that the proliferative capacity of the cells is increased because of the presence of a formative stimulus may be correct, but what the nature of this stimulus may be and how it may effect the mechanism of the cell remain obscure.

"The trend of modern biological research," states Joseph McFarland, "seems to be irresistibly toward the explanation of all vital phenomena on a physico-chemical basis. The striking parallelism that has been shown to exist in the properties and reactions of colloidal and crystalloidal matter in vitro and in the living organism lead to the assumption that protoplasm may be looked upon as consisting of an extremely complex solution of interacting and interdependent colloids and crystalloids, and therefore that the phenomena of life are manifestations of colloidal and crystalloidal interactions of a peculiarly organized solution. We imagine this solution to consist mainly of proteins with various organic and inorganic substances. The constant presence of protein, fat, carbohydrate, and inorganic salts, together with the existence of protein-fat, protein-carbohydrate, and protein-inorganic salt combinations, justifies the belief that not only such substances, but also such combinations are absolutely essential to the existence of life.

"The very important fact that the physical nutritive, or toxic properties of given substances may be greatly altered by a very slight change in the arrangement of the atoms or groups of molecules may be assumed to be conclusive evidence that a trifling modification in the chemical constitution of a vital substance may give rise to a profound alteration in its physiological properties. This coupled with the fact that the differences in centesimal composition have proved very inadequate to explain the differences in the phenomena of living matter, implies that a much greater degree of importance is to be attached to peculiarities of chemical constitution than is usually recognized.

"The possibility," continues the same author, "of an inconceivable number of constitutional differences in any given protein is instanced in the fact that the serum albumen molecule may, as has been estimated, have as many as one thousand million sterio-isomers. If we assume that serum globulin, myo-albumin, and other of the highest proteins may have a similar number, and that if the simpler proteins and the fats and the carbohydrates, and perhaps other complex organic substances, may each have only a fraction of this number, it can readily be conceived how, primarily, by differences in chemical constitution of vital substances and secondarily, by differences in chemical composition, there might be brought about all these differences which serve to characterize genera, species, and individuals. Furthermore, since the factors which give rise to constitutional changes in one vital sub-

stance would probably operate at the same time to cause related changes in certain others, the alterations in one may logically be assumed to serve as a common index of all. In accordance with the foregoing statement it can readily be understood how environment, for instance, might so effect the individual's metabolic processes as to give rise to modifications of the constitutions of certain corresponding proteins and other vital molecules which, even though they be of too subtle a character for the chemist to detect by his present methods, may nevertheless be sufficient to cause not only physiological and morphological differentiations in the individual, but also become manifested physiologically and morphologically in the offspring."

Regarding the hppothesis of Cohnheim that "all true tumors arise in faulty embryonal development," why should nature delay the development of an embryonal cell until adult life of the individual had been reached, a period of forty or more years, at which time tumors usually develop in those susceptible to them? Because a cell is embryonal and is present in adult tissue there is no reason to infer that nature will suspend the operation of her laws governing the development of cells. Every embryonal cell must conform to the degree of development for which it was specialized, that is, grow to maturity and proliferate. If for some reason this is not accomplished it cannot remain indefinitely as an embryonal cell, but will be removed by phagocytic action.

"No one," according to Delafield and Prudden, "has seen the postulated, strayed, or dormant cell of Cohnheim." But such cells have been seen in tissues at certain stages of inflammation, and also during the healing of wounds. If, as has been observed, embryonal cells are sometimes found in tumors, may not their presence be a result of the inflammation which accompanies and precedes a tumor, and furthermore, if tumors are dependent upon injury or irritation for their inception, the presence of embryonal cells in them would seem to be a necessary sequence rather than that they were in evidence as a result of some adventitious event. And, again, it is possible that environment might so affect the individual's metabolic processes that differentiations, both physiological and morphological, may become manifested and account for the presence of atypical cells sometimes found in tumors of different structure, for example, adrenal cells in tumors of the kidney, or cells of sarcoma mingling with those of cancer.

The simple act of planting a twig in the ground illustrates how, through environment, certain morphological differentiations can occur in a cell. The bark of the twig, for example, consists of cells accustomed to the influences of sunlight and atmospheric conditions, but when the twig is planted these same cells adapt themselves to the changed conditions and become root cells, performing a function for which they were not originally designed. "Very remarkable is the case of the brine-shrimp Artemia, as observed and described by Schmankewitsch. One species of the crustacean, *Artemia salina*, lives in brackish water, while *A. milhausenii* inhabits water which is much salter. They have always been regarded as distinct species, differing in the form of the tail-lobes and the character of the spines they bear. And yet, by gradually altering the saltness of the water, either of them was transformed into the other in the course of a few generations. So long as the altered conditions remained the same the change of form was maintained." Accordingly, if it can be reasonably assumed that there is little or no difference between the cell of the protophyta and that of the protozoa similar changes should occur in both, and it may be possible through environment to alter the physiological properties of certain vital molecules to such a degree that atypical cells may become manifested in tissues of different structure. It may be assuming too much to say that this is more than supposition or theory, but nevertheless the term vegetation has been applied to plant-like fungoid neoplasms, or to pathologic tissues of luxuriant growth resembling fungus, to the shaggy appearance of a villous cancer, to arachnoid tufts and villous neoplasms on the pleura and other serous membrance and to adenoid tissue, and their morphological appearance and manner of becoming soft or sloughing resembles to some degree the characteristics of vegetable matter at the stage of rotting. It may be within the bounds of conjecture to assume that the animal cell may possess the property of transmutibility, and, at some period of its existence under certain conditions, return to a vegetable type of cell; a reversionary metamorphosis. The biological relation between the vegetable and the animal kingdoms is so close that from the very beginning a single cell of either one resembles the other, and, in the more advanced forms of life. their manner of existence and their dissolution are remarkably similar. In fact this similarity is found to exist even in pathological conditions such as shock, infections, manner of healing in wounds, parasitic diseases, necrosis, and degeneration of the cell tissues resembling cancer.

In the experiments conducted by Dr. F. C. Wood on explants or tissue cultures, he makes mention of the fact that, "When the tumor is ground up and passed through a Berkefeld filter No. 5, which is impermeable to the *B. prodigiosus*, the resulting fluid is capable of giving rise to a new tumor when inoculated into a susceptible fowl. The obvious interpretation of the phenomenon is that the tumor is transmitted by an invisible and filterable virus." But the fact should be noted that success of the experiment depends upon the fowl being susceptible, or in other words, the fowl must possess an idiosyncrasy; but it cannot be assumed that this idiosyncrasy is similar to that held by the human for chemicals, nor that the tumor is in all respects identical with human cancer, and in the conclusions reached from other experiments Dr. Wood further remarks: "We evidently have here a tumor of an entirely different type from anything known in human oncology." From the technique employed in the above experiment it can be inferred that no living organism exists in the filtered fluid and that the virus must be of a chemical nature.

From the supposed contagiousness of this chemical virus it might be possible to formulate a theory which could be applied to the transmission of cancer by metastasis. For example, a detached tumor cell having traveled by a route offering the least resistance, either a blood vessel or lymph channel, finds lodgment in some favorable location. In its cytoplasm is the active chemical constituent of cancer.

The cells with which it comes in contact in its new location are in a susceptible state and already contain in their bodies the elements, though latent, which would in time determine their passing into a cancerous condition. The presence of the detached cell in their midst, with fully developed virus, serves to activate this latency and they break down; this process being conducted from one cell to another until a fully developed metastatic cancer is unfolded. The fact, however, that metastatic tumors may develop in other parts of the body not in direct communitcation with the blood and lymph channels of the original tumor must lead to the belief that the general constitution of the entire body is cancerous, and that the active agent which started the first tumor is still present in the circulation and capable of giving rise to another.

That the blood and lymph passages leading from the tumor should be by preference the sites of new cancer formations is due no doubt to the presence of the virus in the blood, which, coming in contact with the walls of these vessels, excites the cells into degeneracy.

The invariable presence of the thickened walls of blood and lymph vessels leading from well developed tumors, and resembling somewhat the extended legs and claws of a crab, probably gave rise to the derivation of the word cancer.

In a late brochure (1914) Dr. L. Duncan Bulkley says: "It has been clearly demonstrated that cancer is a disease of civilization, increasing amongst those peoples who previously had been free from it, in proportion as they become associated with those who are more highly civilized, and as they have adopted their customs, and manners of life, and diet, this has been shown in regard to negroes before and after the Civil War, and also as to primitive people in India, Africa, Mexico, Brazil, etc."

The question naturally arises, what can there be other than diet in more highly civilized people that would cause cancer in inferior races that associate with them and, if it is possible to exclude any other factor, the next question which follows is, what can there be in the diet of civilized people which is not found to excess in the foods of primitive peoples? Dr. Bulkley further says that "Williams (in 'The Natural History of Cancer') has collected from all sources the greatest amount of evidence that cancer is relatively rare, and often really unknown, as reported by competent observers, amongst aborigines in the interior of many countries, who live on the products of the vegetable kingdom, with little if any meat secured in hunting." "During a recent extended trip," the same authority continues, "through the Far East I was unable to see or even hear of any cancer, although I met a large number of medical men and made inquiries regarding the same, and visited hospitals with a total of many thousands of patients, in Japan, China, Korea, the Philippines, India, Siam, and Egypt, I met the same response, that cancer was rarely seen among those vegetarian peoples."

That diet has a remarkably beneficial influence upon cancer has been demonstrated by evidence and by observation of competent medical men. "Cancer has repeatedly been observed to disappear spontaneously" (Bulkley). Suspicion has been directed to protein as having some possible cause in the development of cancer from the fact the disease has increased in proportion to the increase in the consumption of meat. However, protein compounds, similar to each other, are widely distributed in the animal and vegetable kingdoms. They are formed by plants, the animal organism receiving them in food, assimilating and metamorphosing them. It is not consistent with facts that protein is capable of causing cancer when eaten in meat, but the same substance, although identical, is curative when vegetables are eaten. Is it not more probable that the improvement observed in cancer patients fed on a vegetable diet is due to the absence of something usually present in a meat diet?

Ehrlich claims that "A tumor in order to grow continuously in an animal requires certain specific substances which permit of its growth, the nature of these substances being unknown; if they are not present the tumor does not grow; when they are exhausted the tumor undergoes spontaneous regression."

The truth of this is self evident from the fact that nothing can grow unless it receives nourishment suitable to its growth, and a tumor must, in order to grow, receive nourishment from the blood, as has been demonstrated by experiments dealing with the transplanting of tumors in chickens and in mice, which show that vascularization must occur in the graft or it will not grow. Accordingly, we may be justified in suspecting that the chemical agents on which its growth depends exist in the blood.

What then may we suppose to be this something, usually present in the meat diet, of universal and increased use in the diet of civilized peoples? Is it not possible that in the profundities and intricacies of scientific investigation we have overlooked the one thing whose simplicity and familiarity have obscured our vision? This something, this one thing in the judgment of the writer, is sodium chloride. In the study of cancer, no one to my knowledge has taken into consideration the possibility of a chemical constitution of the plasma being an agent in the cause of cancer, if not a direct cause. To repeat what has just been said above, "The very important fact that the physical, nutritive, or toxic properties of given substances may be greatly altered by a very slight change in the arrangement of the atoms or groups of molecules may be assumed to be conclusive evidence that a trifling modification in the chemical constitution of a vital substance may give rise even to a profound alteration in its physiological properties."

Granting the truth of this, may we not by an excessive use of salt in our daily food bring about a modification of the chemical constitution of the blood sufficient to cause a profound alteration in its physiological properties?

The plasma is a fluid which must necessarily differ in its quantitative chemical constitution from day to day, never being stable for any length of time. This fickle condition is due to the compositions of the various foods eaten and by the different proportions of salt added to them. At one period the salt content might be very low, and after a meal of salt foods the percentage of salt may rise considerably beyond the normal sufficiently to cause intense thirst.

These occasional variations are not competent to produce any marked effect upon the organism of

youth, but as time goes on the constant use of salt, extending probably over a period of fifty years, must have some influence on the tissues of the body.

The animal economy is capable of an enormous degree of adaptability, it is able to withstand extreme changes in environment, and indeed demands variations, not only in food, but in climate. It is well known that a long continued diet of any one kind of food is prone to induce functional disturbances, such as scurvy for example, and this is also in the use of chemicals or drugs. It is hardly necessary to illustrate this with clinical instances, as every physician is familiar with the pathological conditions of the tissues for example, of the alcoholic, users of morphine or cocaine, and in geophagism.

It is reasonable to assume that tissue changes would occur when the prolonged and excessive use of a chemical, such as sodium chloride, had been indulged in for a considerable number of years. This immoderate use would undoubtedly bring about a modification of the plasma which might be sufficiently potent to exert a deleterious influence on the normal mitosis of the cells. In keeping with this hypothesis is the observation of the frequency of cancer in advanced life, and its almost total absence in infancy and childhood.

If carcinoma were a condition produced by an independent act of the cell at some stage of its division during active proliferation, its appearance should be manifested at any period of life; it should commence with the embryo and be rampant during puberty, the period in which the greatest possible demand is made upon the proliferating functions of every cell in the body. But this is not so, for cancer of an embryo is unknown, and such disease has not been observed in infancy except as sarcoma.

It is a remarkable fact that cancer is fifty per cent. more prevalent in women than in men, and coincidently the percentage of salt in the blood is slightly higher in women than in men. This difference cannot be attributed to chance, but must be looked upon as a circumstance for which nature has a definite reason.

Is it probable that the function of proliferation is influenced by the presence of sodium chloride in the blood? Experiments made by Alexis Carrel and his associates with skin tissue immersed in salt solution, have demonstrated that proliferation could be artificially stimulated and that the rate of growth was influenced by the strength of the solution. It may not be possible to state exactly what the formative stimulus which students of oncology have surmised to exist as the incentive to cancer degeneration, but it can be inferred to be of a chemical nature, and if, by eliminating all other chemical substances which compose the human body, suspicion points to chloride of sodium, it is logical to assume that such a formative stimulus may be found therein.

That salt plays some part in proliferation may be assumed from the fact that animal life is more prolific and abundant in marine waters than is the case with similar species of life inhabiting fresh water streams and lakes. We may recall the autofertilization observed in experiments with sea urchins.

There is no chemical substance in the universe which enters into the body fluids of man in as large an amount as common salt. Of all the substances found in the plasma it heads the list, being from three to four parts per thousand, while few of the other substances are over one part per thousand.

If the adjustment of plant life to the animal is considered from the viewpoint of nature it will be observed that, with the exception of poisonous plants, all the chemical constituents of vegetation have been arranged in proportions best suited to the requirements of the animals that must exist upon them, and to prevent the possibility of an overabundance of any one constituent accumulating in the plasma, a variety of vegetable life was adapted. In our diet, consisting in the main of animal and of vegetable tissues, the proportions of their chemical constituents are left undisturbed, but there is one chemical constituent whose proportion is artificially increased and that is sodium chloride.

We are familiar with the peculiar idiosyncrasies which exist in some individuals for certain foods or drugs, and it is true that what may be food for one person often causes functional disturbances in another. With the elements belonging to the halogen group certain decided idiosyncrasies are commonly observed. For example, when iodine or bromine are administered internally symptoms known respectively as iodism and bromism become manifested in those who possess such an idiosyncrasy. Now the group consists of four elements, namely, iodine, bromine, chlorine and flourine. These elements, which are so closely allied, are all of them powerful disinfectants and irritants, and it could be assumed, that because of this close relation, certain analogous symptoms, which might be termed chlorism, might become manifested in those persons who are excessive users of salt, appearing as an exalted form of cell proliferation or tumor.

The regularity with which cancer occurs in successive generations in some families has given rise to the supposition of heredity. But that a disease capable of transmission of hereditary influence should be delayed until forty or fifty years of life have been reached seems contrary to the general accepted view of heredity. It is more probable that an idiosyncrasy to chlorine is transmitted by the ancestors, and not until the subject has reached middle life, at which time the deleterious influence of an excessive use of salt would have made its presence felt upon the physiological functions of the cells, does cancer develop.

If the chemical properties of the three elements under consideration can be assumed to be similar it may be possible, theoretically, to determine by an examination of the plasma whether a subject, giving a history of cancer in the ancestors, is liable to develop the disease. An excess of salt beyond the normal physiological quantity could be detected by simple tests, and if on the administration of either iodine or bromine evidences of an idiosyncrasy for one or the other are seen it might be safe to infer that the subject is in danger of developing cancer. Of course, as with iodine and bromine, not every patient exhibits symptoms of iodism or bromism, and in fact it requires a lapse of time before such symptoms do appear; and so with chlorine, which is a natural element of the plasma in contradistinction to iodine and bromine, symptoms of chlorism would require years in consuming salt before they would be observed.

If cancer can be shown to be due to the chemical constitution of the blood, the belief held by some that the disease is communicable is without foundation, and it must be looked upon as a purely personal disease inflicted upon the individual by his or her own wilful or ignorant disregard for the moderate use of salt. Theoretically, in order to transmit cancer it would first be necessary to find a subject in whom an idiosyncrasy for salt existed and who at the same time had an active inflammatory condition of some part of the body; into this hyperemic tissue the filtered fluid obtained from macerated cancer tissue might be injected, and a true cancer should develop as a result.

Salt is present in all animal and vegetable tissues, and is a necessary substance in the life and health of animals and of men, but civilization has acquired the habit of using salt on foods to a degree far greater than was possible or even known to peoples of ancient times. Impossible in those days, as the manufacture of salt was practically unknown, and its consumption was in proportion to its scarcity. It may be stated here that cancer was unknown in ages past, and no doubt Aesculapias and other physicians of his period would have made mention of it had the disease come under their observations. However, if cancer has followed civilization, so has the consumption of salt kept pace.

Meat to be palatable must be salted to a degree greater than that which is normally found in the tissues of the animal, and while salt is found in both the animal and vegetable kingdoms, meat contains a much higher percentage than is found in the ordinary list of vegetables used as food. It might be mentioned that the canning industry has been the means of largely increasing the consumption of salt through the variety of foods put up in cans, and that this enterprise is entirely one of civilization. The number of foods savoured with salt can best be realized by enumerating the few in which salt does not enter. Salt, whether eaten on foods, or in canned meats, must eventually find its way into the plasma and increase the saline content of this fluid to a degree higher than that in which the cells were normally intended to live. Furthermore, its inordinate use puts upon the excretory organs an extra burden of removing the excess from the system, the kidneys being the main organs to do the largest portion of this task. The chlorides of the urine are almost an exact measure of the same substances taken in with the food and amount to about 154 to 246 grs. in twenty-four hours. About 150 to 180 grs. are excreted by the kidneys every twenty-four hours beside that found in feces, perspiration, and the tears. The amount of urea excreted by the kidneys varies from about 308 to 617 grs. in the same period. Does it not seem rather unwise to compel the system to excrete an artificially added chemical in almost the same amount as the normal quantity of the products of combustion of the entire body represented in urea?

To summarize all that has been said regarding cancer: Any pathological state of the body must arise from the action of organic, inorganic, or traumatic influences. In cancer, organic and traumatic influences have been eliminated as causes. Considering the inorganic agents as causes all have been eliminated, leaving one only which appears to be the most active cause and this is sodium chloride.

To produce cancer successfully the subject must have inherited an antipathy to chlorine. The manifestation arrives some time during middle life of the individual.

The influence of salt on proliferation and on metamorphosis has been demonstrated. As for hereditary tendencies to cancerous growths, may the part played by heredity in cancer not lie in transmitting to the offspring an antipathy to chlorine?

To the honest sceptic who quite properly characterizes these reflections and suggestions as merely theorizing, the assurance may be extended that, theory though this may be, it is a theory susceptible of indisputable proof. It remains for those members of the profession in control of clinical facilities to conduct dietary experiments by segregating and submitting to a saltless diet certain patients, comparing their condition after a reasonable lapse of time. Regression in cancerous growth in an appreciably larger percentage of those patients on the saltless diet than of those not so treated, would surely be a fact of significance—a fact capable of unlimited confirmation through further experiment.

452 Fifth Avenue.

THE THERAPEUTICS OF URANIUM NITRATE.*

By REYNOLD WEBB WILCOX, M.D., D.C.L.,

NEW YORK.

PRESIDENT OF THE AMERICAN COLLEGE OF PHYSICIANS.

Uranium, a mineral long known in pitch-blende, was isolated in 1789. It was so named from the Greek οὐρανός, the sky, in allusion to the planet Uranus. Uranii nitras,—uranium nitrate,—of the ninth edition of the United States Pharmacopœia contains not less than 98 per cent. of uranyl nitrate $UO_2(NO_3)_2CH_2O = 502.62$.

Source.—From pitch-blende which is an impure uranoso-uranic oxide or from uranite. Either of these, finely powdered, is treated with nitric acid, and various associated metals as lead, barium, bismuth, iron, zinc, radium, and polonium having been removed, uranium nitrate is crystallized from an aqueous solution.

Characters.—Light yellow prisms; odorless and having a bitter, astringent taste; somewhat efflorescent; radio-active, emitting alpha rays and producing a new radio-active element known as uranium-x, resembling thorium, and which emits beta and gamma rays.

Solubility.—In 1.2 parts of water at 25° C. (77° F.); freely soluble in alcohol or ether.

Impurities.—Alkaline earths, heavy metals, iron, manganese, zinc, uranous compounds, sulphates.

Dose, 0.01 gm. = 10 milligm. (1/6 gr.).

Action of Uranium Nitrate.—Uranium nitrate is less radio-active than metallic uranium and some of its salts, but probably this effect is overshadowed by the other manifestations produced by this substance. Its systemic action is similar to that of other metals with an especial paralytic effect on respiration. It is very corrosive and highly toxic.

*Read before the American Therapeutic Society at its eighteenth annual meeting at New York City, June 2, 1917.

Kidneys.—In considerable doses in some animals, when injected intravenously, it produces degeneration, necrosis and desquamation of the tubular and glomerular epithelium with characteristic hyaline droplets in the wall of the capillaries of the glomerular tufts, which are not found in other vessels of the kidney or in other organs. There is, however, no hematuria, in spite of the marked congestion. It generally sets up an albuminuria and glycosuria with possibly an acetonuria, with torpor, somnolence, paralysis, collapse and coma. The glycosuria often develops upon the second or third day of intravenous injection. This may be due to increased permeability of the kidney, for it may appear without any hyperglycemia, indeed uranium salts may even relieve an hyperglycemia if this should be due to a diminished permeability of the kidney. On the other hand, it may of itself produce a hyperglycemia, even if the kidneys be excised, thus pointing to an action which is entirely outside of the kidneys.

The excretion of albumin runs fairly parallel to that of glucose. It has also been noted that nephritic glycosuria and hyperglycemia occur after the administration of many substances, which are toxic as regards the kidneys, such as cantharides, which increases permeability of renal vessels, and chromium, tellurium, mercury, and aloin which cause lesions of the tubular epithelium. The urine is usually alkaline and slightly increased in quantity and in specific gravity for a short period; then it is diminished and when coma supervenes, anuria from obstruction of the tubules by edema and desquamation of cells, is complete. The coma is usually without convulsions unless they are of uremic origin. Repeated injections of small doses result in chronic interstitial nephritis with fibrous changes similar to the chronic diffuse nephritis found in man, but not identical with it for it is not associated with arterial lesions.

The toxicity of uranium salts is probably associated with acidosis because the administration of sodium carbonate lessens this and, as well, diminishes the degeneration of the renal epithelium. The oxaluria present indicates the poisonous effect of uranium and, with the emaciation, denotes impaired nutrition.

Blood.—The blood is rendered less coagulable, although it is not known by what means this is brought about. It also interferes with the restoration of the volume in the blood after saline infusion.

Respiration.—This is at first increased in rate and later becomes slower, while the pulse becomes more rapid, the blood pressure is raised through stimulation of the vasomotor center, and as asphyxia supervenes the temperature is subnormal. Respiratory paralysis causes death.

Alimentary Tract.—There is likely to be thirst, nausea, and vomiting with constipation and later diarrhea. It inhibits the production of ptyalin, pepsin, and trypsin, and its deleterious effects on digestion appear after hypodermatic as well as after oral administration.

Nervous System.—The somnolence, weakness of muscles, and paralysis are usually not marked until a few days before the death of the animals subjected to experimentation.

Anasarca.—As early as 1854 Leconte noted a peculiar dropsy resulting from the administration of uranium salts and this was again studied by Richter in 1904. The anasarcous and ascitic fluid is highly albuminous and is a transudation into serous cavities and into the tissues and may even affect the *fetus in utero*, as was noted in 1905 by Bibergill. This condition is not explicable on the theory of nephritis resulting in anuria, but is probably one due to an altered permeability of the walls of the capillaries, according to the observations of Richter in 1904. This occurs only when animals have been freely supplied with water, otherwise anuria without dropsy will supervene.

In all the animal experimentation it has been noted that dogs, especially the older ones, were more resistant to the action of uranium salts than were rabbits. So far as animal experimentation has gone the intravenous administration of uranium salts produces a characteristic nephritis, glycosuria, and a peculiar edema.

The action of uranium salts seems to have attracted the interest of laboratory workers for a considerable period of time. Among those who have contributed to the pharmacology may be mentioned: 1824, Gmelin; 1851, Leconte; 1888, Chittenden; 1889, Chittenden and Lambert; 1890, Woroschresky; 1904, Richter; 1905, Bibergill; 1906, Fleckseder; 1907, Fleckseder, Hemmeke, Myerstein; 1909, Dickson; 1910, Jackson; 1911, Smith, Pollak, Christian; 1912, Dickson, MacNider; 1913, Franke, MacNider, O'Hare; 1914, MacNider, Myer, Lozzati; 1916, MacNider, Bogart, Underhill, and Mendel.

Therapeutics of Uranium Nitrate.—It has been used in England as a spray for the throat in 2 per cent. solution, with caution, for various conditions.

In 1895 Samuel West published the results of his observation of two patients suffering from diabetes mellitus; one a lad of twenty-two years, the other a woman of forty-five years. Later in the same year he added the records of one hospital and some other patients, but without complete details. He employed at first uranium nitrate and the double chloride of quinine and uranium, but finding no difference between the two salts, finally decided upon the former as equally efficacious. He was apparently familiar with the observations of Chittenden upon the inhibition of the activity of ptyalin after small doses of the drug and in larger quantity its effect upon pepsin and trypsin. He found that the drug, when administered by the mouth, acted slowly and that small doses (one-sixth of a grain) were as efficacious as larger ones (one grain), and finally that some tolerance of the remedy was apparently established.

He concluded that the general effects were as follows: After a short time all patients reported that their thirst was greatly relieved and that the frequency of urination and the quantity of urine was greatly reduced. If the sugar is largely influenced by diet the remedy is most useful on account of its physiological effect in digestion. If dieting and ordinary treatment have produced all the results of which they are capable, further improvement takes place after the administration of uranium ntrate. This result may be due to the slowing of digestion of starches and some forms of albumin, and the remedy may be especially useful in controlling excessive pancreatic digestion.

No uranium is found in the urine, probably because none gets into the general circulation. It may, however, pass from the intestines to the liver and, having been excreted in the bile, again pass into the intestines. Although the author recognizes the fact that when it gets into the blood after hypodermatic injection it is an active poison, he believes that when introduced into the stomach it is not toxic because of its imperfect solubility and absorption. He reports that he has administered from fifteen to twenty grains, thrice daily, without symptoms of gastric irritation.

His method of administration was as follows: Commence with a small dose—one or two grains—and increase slowly after an interval of a few days until the desired effects are produced. The remedy is best given freely diluted with water, after food. He never observed any disturbance of digestion nor irritation of the stomach or of the bowels, nor that its prolonged administration caused glycosuria. The statements made by other authors, that it reduces hemoglobin and therefore the oxygenating power of the blood, were apparently not confirmed by the author, since he makes no mention of such results.

In the treatment of diabetes mellitus I have long since abandoned a strict antidiabetic diet excepting for experimental purposes while determining the character and severity of the disease, which should be considered rather as a symptom-complex of which persistent glycosuria, polyuria, thirst, emaciation, and weakness are prominent manifestations. On a diet as near normally balanced as is possible, due regard being paid to total quantity of food-intake, the dangers of excess of proteids, as indicanuria, purinemia and autointoxication on the one hand, and from lack of sufficient carbohydrates, as acetonuria and coma, on the other, are avoided. If the nutrition of the patient can be maintained, infections such as tuberculosis and septic conditions, as well as gangrene, are exceedingly rare. So far as drugs are concerned their use is largely symptomatic; the opiates, and particularly codeine, the organic bases and nitrogen-benzene derivatives, especially antipyrine, and the volatile oils acting chiefly on the central nervous system, as valerian, all have their uses but are not to be considered as constituting treatment. Benzosulphinide is, of course, a condiment and should be used in much smaller amounts than is ordinarily directed, not because it is harmful, for it is not, but for the reason that smaller amounts are quite as efficacious and satisfying as sweetening.

The arsenic-lithium carbonate ordinance in carbonated water, devised by my old teacher, Martineau, which I learned while a student in Paris in 1882, is probably more frequently useful than any single medication, and particularly in diabetes mellitus of hepatic origin.

Patients suffering from diabetes mellitus treated with discrimination after a thorough study so that the cause shall be accurately determined do not die from the disease or its ordinarily associated sequelæ. My oldest patient has been under my care for thirty-two years and has now reached the age of fifty-four. Often months pass without glycosuria or possibly with only traces of glucose in the urine.

On looking over my practice for the past twenty years I find one hundred and eleven instances of the various forms of diabetes, classified as follows:

Diabète azoturique.—If one considers the pharmacology of uranium, by analogy it should be influenced by this remedy. As a matter of fact, of seven patients suffering from this disease, none were benefited, and presumably the drug was without effect.

Diabetes alterans.—Three patients received uranium nitrate as a part of their treatment, but without any appreciable results.

Diabetes mellitus.—Nine of the neurotic type were apparently uninfluenced, as to their glycosuria, by the remedy. Of the hepatic type, fifty-four received the remedy, including six (three pairs) of the conjugal variety, and forty-six apparently received benefit in that thirst, polyuria, and glycosuria were improved, but generally only so long as the remedy was continued. The usual daily amount administered was from one-half to one and one-half grains; on a few occasions it reached three grains. Pancreatic diabetes naturally varies within wide limits owing to the diverse conditions affecting the gland. Of twenty-seven patients, twenty-two were improved as to the symptoms above noted, temporarily at least, but it was with difficulty, if at all, that any really lasting benefits could be obtained.

Diabète bronzé.—In two instances, in which uranium nitrate was employed absolutely no results were obtained. Of the infections, those due to syphilis, as paresis or tabes, or disseminated sclerosis, the disease seemed to be of more importance than the glycosuria, and no use has been made of the remedy. No patient under my care suffering from exophthalmic goiter has ever shown diabetic symptoms or signs, therefore no observations upon the effect of uranium nitrate have been made. Nor have I ever encountered diabetes as a sequela of typhoid or relapsing fever, or of cholera or diphtheria.

Diabetes insipidus.—Nine patients which have been under observation received uranium nitrate in daily amounts of from one-half to one grain. There was no reason why this remedy should influence the polyuria, nad as a matter of fact it did not. In a disease of so obscure an origin and of so unsatisfactory a course and so little amenable to treatment one sometimes yields to temptation and embarks on therapeutic adventures.

In all the instances in which I have employed uranium nitrate I have never noted any untoward gastric or intestinal symptoms nor any signs of blood or renal disturbances; careful observation has been especially directed toward the early detection of the latter. In some instances, especially in the hepatic and pancreatic forms of the disease, the remedy, when its use has resulted in the diminution of glucose to a trace or to total absence, has been continued for months and, for some patients, for years.

On conclusion, I believe that the statement as to the therapeutics of uranium nitrate, which I quote from the tenth edition of my Materia Medica and Therapeutics, is a fair one: Internally it has been employed with good effect in the treatment of diabetes mellitus for at least two decades. It will at times markedly diminish the amount of glucose in the urine, and this diminution, often to traces, will

persist so long as the remedy is continued. In other instances it is entirely without effect. Its use then is purely empirical, without any basis for an opinion whether it will or will not be useful. Indeed, when its use is successful in reducing glucose, lessening thirst, weakness, and emaciation, there is no valid explanation of its action.

Fortunately in diabetes the urine is frequently examined so that structural changes in the kidneys are readily and early detected and the treatment at once abandoned. The digestive disturbances also give early and emphatic warning. On the other hand, it has been administered in large doses, and over long periods of time, even years, without any digestive symptoms or renal signs, with apparently great benefit to the patients suffering from actual diabetes mellitus.

679 Madison Avenue.

THE TONSILS AND RHEUMATISM.

By ALBERT BARDES, M.D.,

NEW YORK.

OTOLOGIST AND LARYNGOLOGIST, FLUSHING HOSPITAL AND QUEENSBORO HOSPITAL.

Of late there has been some controversy over the merits of tonsil removal for the relief of rheumatism. Opponents of the procedure maintain that the operation generally fails to benefit the disease and that in many instances it has increased the suffering rather than diminished it. This is at variance with the experience of most of the men engaged in throat work. During the past ten years I have enucleated the tonsils of some two hundred patients for rheumatism and kindred disorders. To the best of my belief not a single person was made worse by the operation. Nearly all were benefited and many were wholly cured. About a score of my patients had been climate hunters unable to withstand the rigors of our northern winters. The success of my work has convinced me that just as the tonsil operation is the panacea for the ills of child life, its field of usefulness is quite as extensive in middle life.

For a long time physicians have been strongly impressed with the frequency with which tonsillitis was followed by rheumatism. The association occurred too often to be accidental. It was well known that an epidemic of tonsillitis is generally followed by an epidemic of rheumatism. Grebe of Jena was the first to establish a connection between the two. He found that rheumatism is a blood infection and that the infecting organisms that are found in the swollen joints, in the blood, and in the urine of sufferers are identical with those commonly found in the throat and particularly in the tonsils. Ten different organisms have been found in the joints of persons with rheumatism. In particular there is a streptococcus, known as the *Micrococcus rheumaticus*. Sometimes it becomes a diplococcus and it is a normal inhabitant of the tonsils.

As many as 150 kinds of germs have been found in the throat of a healthy person. Most of them are of no significance excepting for the putrefactive changes they promote and for the foul odor they impart to the breath. Of course the nose and the throat constantly harbor disease germs but these are incapable of mischief so long as the upper air passages are in a healthy state. It seems that the normal secretions of the nose and the throat wash away offensive organisms before they have a chance to colonize. The crypts of the tonsils at all times contain myriads of disease germs in a quiescent state. As soon however as the throat becomes disorganized, its bactericidal power becomes impaired and the tonsillar pockets become ideal culture tubes for erstwhile innocuous bacteria which now become virulent germs. The proximity of the tonsils with the cervical glands affords the germs a ready passage to the circulation. The readiness with which streptococci attack an enfeebled throat is instanced in the manner in which they hasten the destruction of an area already invaded by cancer, tuberculosis, or syphilis.

Unquestionably attacks of rheumatism can come from a suppurating focus anywhere in the body. Witness the arthritis of gonorrhea and of the puerperium. Also the infecting pus can come from the teeth, from a discharging ear, or from the nasal sinuses, but the vast majority of the attacks can be traced to the tonsils. At any rate it is an attack of tonsillitis that disurbs the equilibrium of the throat, fans the smoldering flame, and causes the absorption of the toxic products. Wood of Philadelphia, experimenting upon swine that have well defined tonsils, found that systemic infection occurs sooner and with greater violence when the infecting virus is rubbed into the tonsils than when it is applied elsewhere to the throat or is mixed with the food. The belief is gaining ground that it is principally through the tonsils that most systemic infections, notably tuberculosis, enter the human organism.

That rheumatic fever is a true pyemia is shown in that the symptoms are those observed in all septic intoxications. They are chills, febrile remissions, sweats, anemia, high leucocytosis, and a partiality for serous surfaces. The distinguishing feature of rheumatic fever is the marked acidity of certain of the body fluids, such as the urine and the sweat, which are normally alkaline. Frequently even the breath has a sour odor.

The older writers disclaimed any connection between rheumatic fever and chronic rheumatism. The present belief is that the difference is one of degree rather than of kind. The former being caused by the rapid absorption of toxins, which overwhelm the system and produce a severe reaction, whereas the latter is due to the occasional and restricted absorption of toxic products. An attack of rheumatic fever does not begin to decline until sufficient antibodies are manufactured in the body to overcome the toxins. Normally the blood is strongly bactericidal but occasionally it favors rather than hinders germ proliferation. Latent attacks of rheumatism are probably caused by the retention in the tonsils, or elsewhere of infectious materials which is thrown into the blood stream whenever conditions for germ growth are favorable.

The great joints, the heart, and the pleura are the places most susceptible to the corroding influence of the rheumatic infection, although no serous surface is free from attack. The temperature in rheumatic fever seldom exceeds 103° F. When it does so it denotes an attack upon a vital organ. An abrupt rise in the temperature usually signi-

fies a fresh onslaught of the infection and a sharp pain generally indicates the place where the toxin has been concentrated. The heart becomes infected in over a third of the sufferers of rheumatism. Usually the mitral valves become eroded—betrayed by a blowing systolic murmur over the apex of the heart.

There are three stages in life when the throat is especially assailable. In infancy, in adolescence, and in middle age, and these are the periods when rheumatism is most prevalent. Formerly it was thought that rheumatism is rare in infancy; it is now claimed that most of the graver respiratory and circulatory diseases of babyhood are of rheumatic origin. The belief is fostered by the knowledge that nearly all the ailments of a young child start with tonsillitis. Pyelitis, intestinal disorders, and growing pains are generally but signs of a rheumatic infection.

Youth is the time when the danger from a rheumatic infection is greatest. The most dangerous period being between the ages of 13 and 18 years. During adolescence gland life is exceedingly active and the dissemination of septic products is promoted. Frequently it is easy to trace the relationship between an attack of tonsillitis and one of rheumatism, since symptoms of the latter affection set in ere the tonsillitis has subsided. Usually, however, a week or two separate an attack of tonsillitis and one of rheumatism.

Following puberty girls are the principal sufferers of rheumatism and the heart is their most vulnerable organ. The aftermaths of rheumatism in young girls are many: goiter and chorea are among them. The sexual change and the resulting anemia have a disturbing influence upon many young girls. It places a severe tax upon their vitality and the heart becomes a ready prey to a rheumatic infection. Frequently an important organ is crippled for life, and often the way is prepared for a tuberculous infection. After a girl has matured and especially after the eighteenth year, her frame assumes greater stability and thereafter the consequences of a rheumatic infection are less serious than among males.

In middle life nearly everyone suffers more or less from rheumatism, or from one of the many disturbances akin to rheumatism, such as neuritis, bronchitis, asthma, gout, and various affections of the skin, of the alimentary tract and of the genito-urinary system. From the fact that most of the diseases of the ear and of the upper air passages begin with a sore throat, it is fair to assume that they too are of rheumatic origin.

Between the ages of forty-five and fifty-five years rheumatic affections are more prevalent than at any other period in life. This is the time when important organic changes are taking place and vascular pressure is at the maximum. It is with fear and apprehension that many women look forward to the change of life, and both their real and their unreal ailments are ascribed to it. Statistics show, however, that the ills of middle life are far more dangerous to men than to women. There seems to be a close relationship between the sore throat of middle-aged men and the acute affections that often prove fatal, especially pneumonia and kidney disease.

Many middle-aged individuals, through their enervating habits of life become predisposed to rheumatism. These are the so-called lithemics, people who partake too freely of highly nitrogenized products and who get insufficient exercise to help carry off the waste products of this rich food. The natural effects of hypernutrition are faulty elimination and autointoxication. The chemistry of the secretions is changed and acidosis occurs. Severe headache and frequent attacks of coryza often result therefrom. Rheumatism has long been regarded as a family failing, an inherited disorder, but according to our present knowledge germ diseases are not transmitted from parent to child. What can be inherited however are certain anatomical defects of the nose or of the throat, which conduce to rheumatism.

The throat of lithemics is often the barometer of their physical well-being. It is apt to be supersensitive and easily deranged. Inspection usually reveals a livid pharynx and injected tonsil pillars. Most likely there is an abundance of lymph substance in various parts of the throat, especially upon the base of the tongue. Common complaints are a feeling of dryness in the throat, some hoarseness, and perhaps a dry harsh cough. This hoarseness may cause much concern from the thought of malignancy. Rheumatic arthritis of the larynx is a common complaint. In most people with rheumatic affections the tonsils cannot be seen, as they are shrunken and lie deep in the throat, beneath the tonsil pillars. When the submerged tonsils are drawn to the surface foul-smelling cheesy masses, or perhaps tonsilloliths, can be squeezed out of them. These foreign bodies often are the cause of much annoyance and keep the throat in an inflamed state for a long time. The condition of the tonsils rather than their size determines whether or not they are diseased. Contrary to the general belief tonsils that are large and that stand out prominently in the throat are generally harmless, for usually their crypts are patent and drainage is ample. The principle objections to them are that they present a large infectious area and occasionally they interfere with the functions of the throat. Quinsy or peritonsillar abscess rarely starts in a large open tonsil. It comes from infectious material in a closed tonsil, which, in seeking an outlet at the place of least resistance breaks through the capsule of the tonsil and infects the peritonsillar space. This painful affection is rare in children because their tonsils are usually yielding and the crypts are open.

Acute tonsillitis is the most common and frequently the most depressing of all acute infections. The debility comes from the toxemia and it deranges the entire system. Until recently the treatment of this disturbing affection has been far from satisfactory. Most local applications had but a moral effect. In my hands the standard remedies, argyrol and silver, seldom influenced an attack. It was not until I was led to cleanse the tonsils with alcohol and then to rub in finely powdered aspirin, that I found that tonsillitis was brought under better control. It seems that the alkaline secretion of the tonsils converts the aspirin into nascent salicylic acid, the action of which is dual. It relieves the soreness and it inhibits bacterial growth; swallowing becomes eased,

and the extent of the inflamed surface becomes reduced. A further advantage of using aspirin in this way is that rheumatism is less apt to follow than when it is omitted. It has been found that the treatment of rheumatism in any stage is facilitated by rubbing aspirin into the tonsils. The symptoms are controlled quicker than when the drug is given internally and, besides, the dose is much smaller. Nor is it attended with the unpleasant after effects that mar the benefits of the salicylates in susceptible persons. Numerous persons have been consigned to a life of invalidism through the injudicious use of these drugs. Head noises, deafness, vertigo, headache, nausea, excitability and pronounced anemia are some of the conditions produced by the salicylates.

From the earliest known time the tonsils have been regarded with suspicion, as being accountable for many systemic disorders. They have been attacked in every conceivable way, but with indifferent success. Physicians have hesitated to remove the entire tonsils for fear of destroying essential functions, and from fear of hemorrhage. This leads to the consideration of the uses of the tonsils; a subject of much speculative thought. It seems that they are vestigial organs like the appendix, which evolution has rendered worthless excepting in infancy. From the fact that ruminating animals use their tonsils to moisten and to lubricate the dry fodder upon which they subsist, it is assumed that the human tonsils served a like purpose in the early stage of man's development, when his food consisted of nuts and herbs.

All young infants have a certain amount of adenoid and tonsil tissue. It takes the place of the salivary glands until mastication becomes established, at about the eighteenth month. After that the tonsils and adenoids gradually disappear, unless they are diseased, in which case they continue to grow until puberty. Then they become smaller but they remain diseased. It is seldom that a child outgrows diseased tonsils. One thing is certain, diseased tonsils are a menace to any child. Even in infancy they are harmful rather than useful and they should be dealt with at the earliest possible moment. That the tonsils are not essential even to nursing infants is proved by the fact that their removal is not followed by any discomfort.

Tonsil surgery was in a chaotic state until the old and discarded operation of tonsil enucleation was revived and modified. This has placed tonsil surgery upon a scientific and safe basis and has enabled us to combat successfully systematic infection from the tonsils. No doubt the old way of removing a portion of the tonsils did some good in reducing the area of infection, but it seldom effected a cure and often caused dangerous bleeding. Frequently it led to severe disturbance by sealing the outlet of infected crypts. No tonsil operation is complete unless every infectable pocket has been obliterated. In middle-aged persons not only should the tonsils be dissected out clean, but all diseased lymphoid tissue in the pharynx and upon the base of the tongue should be destroyed as well. Likewise the drainage of the nose should be improved if necessary, by surgical means.

The operation of tonsil enucleation is applicable at any age. Mishaps are extremely rare. My youngest patient was an infant of two years; my oldest a man of seventy-five years. In nursing infants it seems best not to remove the entire tonsils. The voice is not affected by removing the tonsils, providing the tonsil pillars are not injured. Madame Patti is one of the many noted singers whose tonsils have been removed. The tonsils and adenoids of children should never be operated upon without ether. Never chloroform. Novocaine anesthesia suffices for most adults.

164 West Seventy-third Street.

A CONSOLIDATED NURSING SERVICE.

By CREIGHTON BARKER, M.D.,

NEW YORK.

Coincident with a keener appreciation of the value of the educational and preventive phases of public health work the trained nurse has become a more necessary part of all municipal health organizations. It is not to the credit of health officials to state that they were tardy in realizing the value of the public health nurse, but it is a fact, nevertheless. To the nurses themselves belongs the credit for first appreciating the great service that could be rendered by nurses visiting the homes of the indigent sick. By organizing themselves into visiting nurses' associations and securing their own funds they have in the past fifteen or twenty years laid the foundation for what is now conceded to be one of the most important of all public health activities. One of the earliest, and certainly the most active, of such associations is the Henry Street Settlement of New York City. Under the guidance of Miss Lillian D. Wald this organization has solved many of the visiting nurses' problems, and has an enviable record for many years of splendid service.

The charters of many cities still make it impossible for the health department to employ nurses. As recently as 1914 the health department of one of the most progressive cities in the Middle West, realizing the value of the trained nurse as a health agent, found that under the existing laws it could not employ nurses, and was forced to appoint and carry them on its payroll as sanitary inspectors. This state of affairs existed in a city that employed, and still does employ, four plumbing inspectors in its health department. Certainly modern ideas of disease prevention are slow in being accepted when one finds sewer gas receiving so much attention and no provision for nursing service.

But the old order changeth. With the advent of a group of trained public health officials who think for themselves, and are not bound by any archaic traditions, the value of the trained nurse is being fully appreciated. Such health officials desiring visiting nursing service are, however, confronted with a peculiar problem.

Nearly every city of any size has one or more visiting nurses' associations, supported by private philanthropy, and usually upon a sound financial basis. These associations have their traditions and ideals of service, the nurses on their rolls have in many instances been in the employ of the association since its beginning, and their strength, their minds, and in some cases their very souls, have been

given to make the name of the visiting nurses' association synonymous with charitable service of the highest type. To disband these existing organizations and transfer the nurses to the employ of the local health department would not only be impossible in most cases, because of sentimental reasons and traditions, but in every instance impracticable because of the expense involved. These nurses may, however, be placed under departmental direction.

The problem that then arises is to coordinate the activities of these various units into a workable organization under the direction of the health department. This, as a purely administrative problem, appears simple enough, but it is certain to be attended by a variety of difficulties. Personal and quasi-political objections are invariably encountered. The various organizations are unwilling to give up their established policies and independence of action, and occasionally a disgruntled subscriber will withdraw his support. In this regard, however, each community presents a peculiar problem, with a local means for solving it.

The great obstacle that stands in the way of combining the existing units into an efficient organization is the fact that usually each of the independent associations has a specialized function. That is, there will be a tuberculosis nursing association, a child welfare organization, a maternity nursing association, and frequently other groups organized for especial service in which some philanthropic person was interested or for which there existed a particular need.

To place these various organizations under the direction of the health department and allow them to continue their specialized function perpetuates a system involving a duplication of effort that is at once costly and inefficient. To state an example: A mother living in A Street has recently had a baby; in the tenement upstairs is a man suffering from tuberculosis, and awaiting a vacancy in the sanatorium; and across the hall is a schoolboy detained at home with tonsillitis. This house receives the services of three nurses from as many different organizations at the same time. The nurse from the maternity clinic attends the mother, the nurse from the association for the prevention of tuberculosis visits the man, and the school nurse attends the boy. This is not an overdrawn illustration, and not infrequently two nurses will make the greater part of their daily rounds together, visiting the same houses and often the same families. In addition to this costly duplication of service, the maternity nurse that visited the mother in A Street may not have another case in that locality, and will spend an hour or more getting to her next case, which is in Z Street.

Such a state of affairs is bound to appear to the unbiased observer as a gross waste of time and energy, and yet it is the situation that existed in Los Angeles and Dayton, and still does exist in a similar form in many other cities, including New York.

The logical solution of the problem is reached by the installation of a district nursing system. After a careful analysis of the nursing needs, and a consideration of the transportation facilities of the various areas, the city is divided into a number of districts. A nurse should be assigned to each of these districts, and it should be her duty to perform any and all nursing service required by the indigent residents of her district. The nurses should remain in the employ of the existing private agencies, and, so far as is possible, the desires of these organizations should be followed in assigning districts to nurses. The assigning of cases within the various districts should, however, be under the supervision of a director of nursing service employed by the department of health, and her office should serve as a clearing house for all visiting nurse service in the city.

The director of nursing service should be a woman of tact and possessing more than ordinary executive ability, for upon her will rest the responsibility for the success or failure of the consolidated system. She should be competent not only to direct and instruct the nurses, but to formulate policies, construct work programs, and, in conjunction with the health officer, map out and execute educational campaigns. Her subordinates, the district nurses, are in more intimate contact with the people than any other public health agent, and she can develop a wide and valuable influence, hence the choice of a person to fill this position should be wisely made.

There are specialists in public health nursing that will not agree with the plan herein set down. Some of them will object because, for some personal reason, they wish to see the present independent organizations continued. Others will object, with the contention that nursing service requires specialization. This reason is scarcely valid, however, for it is safe to assume that any nurse after completing the present-day course of training in a good hospital is competent to render any service that district nursing may demand. The objections to the plan are not real, and in cities where it has been tried out there has been found much to commend it in the economy of operation, definitized control, and increased service.

THE RELATION OF CAPILLARY CALIBER TO NORMAL AND PATHOLOGICAL SENSATION AND FUNCTION.

By W. V. GAGE, M.D.,
WORLAND, WYOMING.

My object in presenting this paper is to ascertain, through criticism, the opinions of the profession, regarding the truth or fallacy of the theory presented. I realize very fully that I am offering something new, when looked at in the mass, and I shall probably make statements which are faulty, but it seems to me, nevertheless, that many points brought out must appeal, upon analysis, as being astoundingly evident.

In order to introduce the subject properly, I will state that this paper is based upon the theory that normal sensation and function demand a perfectly balanced capillary circulation, and that a nerve is a carrier of stimuli alone, and not an originator of either function or sensation. Contraction or dilatation of the capillary system of a given organ is back of its various physiological functions, and I believe, just so surely back of the pathological vagaries called disease.

Normal blood supply means perfect physiological functioning, without abnormal sensation, while capillary instability, either permanent or transient, spells pathological sensation instability.

I will state in order, ideas regarding a few of the common sensations which, to me, seem to prove the rôle of the capillary as the principal factor in their production.

The sneeze, which goes with a common cold, is the result of a perversion of sensation due to capillary dilatation in the turbinates and the septum, and immediate relief follows the local application of adrenalin, and consequent capillary contraction.

The variations in the sense of taste and smell, which accompany a common gold, are not due to nerve perversion, but to the inability of a congested mucous membrane to properly interpret a given stimulus, and the watery eye and the abnormal nasal secretion have back of them the dilated capillary.

Cough is an effort upon the part of nature to "scratch" by forcible air expulsion, a mucous membrane showing a perversion of sensation, because of capillary dilatation, and this sensation is as truly an itch as that found in an eczema or an urticaria, and is based upon the same causative factor.

Consider the part played by the dilated capillary as a function perverter in the photophobia which goes with a number of inflamed eye states. Headache and migraine are perversions of sensation due to over dilated or over contracted cerebral and meningeal capillaries. Tinnitus is a perversion or exaggeration of sound perception, due to either transient or permanent local capillary dilatation.

Every perversion of the special senses, outside of those due to anatomical anomalies or traumatic injury, has back of it a dilated or a contracted capillary. Pain of every character, outside of that due to actual nerve trauma, has as a concomitant, congestion or anemia of the painful part, and usually nothing has happened to the nerve, supplying the part, it simply acting as a conductor of the sensation induced by the abnormal blood supply.

Sensations of heat and cold are both influenced by the blood supply of the part tested, and a simple method of demonstrating this fact is to render a finger either bloodless or congested, by the use of a constrictor, and then note its inability to properly appreciate the different degrees of heat and cold to which it is subjected. This is especially true where the finger has been wrapped from tip to base with a narrow elastic bandage, and a constrictor applied to maintain the bloodlessness. The part so handled is especially slow to respond to sensations of heat or cold, or to a pin prick, and experiments convince me that many minor operations may be done with little pain upon fingers and toes rendered bloodless by the above method.

Everything that I can say in this article, has been said for years in the few words which give the classical symptoms of inflammation, *i.e.*, tumor et calor et rubor et dolor, but, as so often the case, we are deaf and blind to the simple and obvious.

All the sensations which precede and accompany the sexual act, from the blush of suggestion to the ejaculation of the semen, have the dilated capillary as a causative factor.

The tingling pain caused by capillary over dilatation consequent upon exposure to extreme cold is a familiar example to us all, and the numb, peaceful, painless death which intervenes when the exhausted capillary begins to contract, after prolonged exposure, gives a clinical picture of actual total anesthesia due to capillary contraction. A few of us have experienced the agonizing pain which accompanies the capillary dilatation which follows when half frozen hands or feet are subjected to a higher temperature.

It should be borne in mind that in the production of the various symptoms which go with the picture above, no change has taken place in the nerves supplying the parts. They have remained quiescent, and simply acted as conductors of sensation only.

The pains of caisson diseases, the "bends," will well illustrate the eccentric tissue reaction due to variations in the blood supply to the whole economy, when the capillaries endeavor to accommodate themselves to the excessive variations in atmospheric pressure.

The sensations which go with the manifestations of hunger, laughter, anger, fright, nausea, or sweating or any of the sensations to which mankind is subject, will eventually be proven to depend upon capillary caliber.

The white wheal and consequent bloodlessness and anesthesia which follow a hypodermic of distilled water into the tissues, well demonstrate the contracted capillary's antagonism to pain.

The peculiar degenerations and diseases of old age have, for ages, been unheeded orators, shouting at us to note the degeneration that must inevitably follow in all the tissues after age removes, together with its elasticity, the ability of a blood-vessel to properly respond to the physiological demands of a given organ, either in the matter of function, nutrition or protection.

Dyspnea, and its accompanying symptoms, is due to a dilitation of the lung capillary and a consequent compression of the air cell, the air hunger, blueness of face and extremities being consequent upon the fact that an insufficient air cell area is left, on account of capillary compression, to properly areate the blood brought to the lung from the economy.

A contracted lung capillary could produce symptoms of dyspnea for, while in the latter case, the air cell would be correspondingly dilated, the contracted capillary would not present sufficient blood carrying area to the dilated air cell, and air hunger would follow. The immediate relief that follows the hypodermic use of adrenalin, in the dyspnea of asthma, with the dilated lung capillary, is proof positive as to the pathologic state that exists.

I would state in parenthesis, that about eight years ago I tried to make the above statements regarding dyspnea in the columns of the *Journal of the A. M. A.*, but the editor refused me admission because he believed my article to be too theoretical, and three or four years later I was compelled to submit to seeing others receive credit for priority, regarding this and several other discoveries regarding adrenalin, which were discussed in the same article.

Among the statements made in the paper referred to was one which might well be embodied in the

present article. It is ancient history now, but I believe that when first written it was absolutely new, *i.e.*, "I wish to state that an over dose of adrenalin will produce symptoms similar to those which we see in fear, fainting, shock, profound anesthesia, epilepsy, etc.; *i.e.* pallor, tremor, sweating, prostration, vertigo, and spasm. It is possible that the symptoms enumerated above, when found in the diseased states mentioned, are due to a more or less sudden liberation of a surplus of the adrenal secretion."

The probabilities are that future investigation will show that normal, elastic blood supply to a part means normal functioning, and that a plethora or an anemia means, when transient, a perversion of function and when established, a pathologic state, and that the sneeze or cough or pain or photophobia or tinnitus or nausea or sweating, are simply jangles or sparks from our conducting wires, giving early warning of future faulty metabolism and later pathologic states.

The flow of all the secretion of the body, whether from duct or ductless gland, is normal so long as the blood supply to the gland is normal, and it becomes a pathological product, under the influence of prolonged capillary dilatation or contraction, and diseased states are produced, not only because of interference with the functioning of the gland itself, but because of conditions consequent upon the inability of dependent organs to properly metabolize and appropriate a secretion which is chemically lacking.

All the tissue changes which we observe in overgrowth or eccentric growth of normal structure, which eventually produce either benign or malignant tumors, have back of them an increased blood supply, while atrophy and necrosis and death follow obstruction to the blood supply of a part.

Capillary dilatation and the diapedesis of the corpuscle in inflammatory states are too well known to be commented upon, and I mention them only as another link in the chain of proof as to this state as a factor in over functioning.

It should not be hard to prove that the various results that have been obtained in the use of the numerous local anesthetics were due as much to "blood block as to nerve block."

I can see so much that I am actually able to put my finger on, in this matter of parallelism between blood supply and sensation and function, and so much that is hard to classify under the certain head of fact or theory, that I have been baffled at many points, but I feel sure that once you start thinking along this line, I shall not be alone in the matter.

When considering this subject, please put in a good portion of your meditative hours comparing the difference in the possibilities of tissue metabolism, in an individual of "blushing age," *i.e.*, the age of the elastic capillary, and one where years and consequent loss of capillary resiliency render blushing difficult or impossible.

All the diseases of old age can have back of them, the inelastic, incompetent capillary, and we shall surely find that old age means this and nothing else.

Take conditions as widely separated, apparently, as baldness and necrosis, as an erection and a rheumatic joint, as a cough and an urticaria, and consider the influence of physiological and pathological blood variations, in the production of both function and sensation, and you are astounded because of the bigness of the subject, and the ridiculous simplicity of the fundamental principle which underlies the whole matter, provided the author of this paper is on the right track.

The dilated capillary seems to go hand in hand with over functioning or overgrowth of a given part, even to the point of malignant growth production, while the contracted capillary seems to spell under functioning, atrophy, anesthesia, necrosis, and death.

That sensation and function both normal and pathologic are absolutely dependent upon capillary caliber, to me seems indubitable, but the blank wall which stands between me and the absolute rounding out of my argument is the gap that exists between capillary caliber variation and the terminal nerve filament.

To me, the unanswerable query is: "What has happened as a result of capillary dilatation or contraction which stimulates the nerve filament to record sensation, either normal or eccentric?" Does some change in function or sensation take place because of simple pressure or the lack of it, or do as yet unidentified components of the circulating blood produce variation in function or sensation by actually filtering through the capillary wall, as do the leucocytes in inflammatory states.

One point that should be borne in mind in the consideration of this subject is that in diseased states of the blood, as in the anemias, one would have to consider faulty blood chemistry as an added factor, along with capillary instability, as an influence in pathologic processes.

I shall very much appreciate hearing from any reader of this article, either in criticism or commendation, as I am anxious to compile ideas along the lines suggested, the major portion of which I have scarcely touched upon.

113 Big Horn Avenue.

OBITUARY OF JULIUS H. EICHBERG.*

By CHARLES D. AARON, Sc.D., M.D.,

DETROIT, MICHIGAN.

Julius H. Eichberg was born in Petersburg, Va., in 1859, and died in Cincinnati, Ohio, Nov. 1, 1916. In his early youth he studied in Germany, completing the course in the gymnasium. Thus was laid the foundation of the scientific attainments and exemplary scholarship which distinguished his later years.

In 1880 he was graduated from the Cincinnati College of Pharmacy, after having been associated in chemical laboratory work with the elder Fennel, a noted pharmacist of those days. Eichberg must have been a student of rare assiduity and talent, for he carried off honors and a gold medal at his graduation. In 1887, in recognition of his ability, he was appointed pharmacist of the City Hospital. He was not satisfied, however, with his educational equipment, despite public recognition and encour-

*Read at the seventeenth annual meeting of the American Therapeutic Society, New York, June 1 and 2, 1917.

agement. In 1891 he registered as a student in the Miami Medical College; four years later he became an interne at the City Hospital, and after a short service in that capacity went to Vienna to pursue special studies. Upon his return he engaged at once in the practice of his new and what was destined to be his life-long profession, and soon won the confidence of his patients and the respect of his colleagues.

It was natural for him that he should continue his helpful work as pharmacist in the capacity of Professor of Pharmacology in the College of Pharmacy, but he soon added to his academic labors those of Professor of Materia Medica and Therapeutics in the Ohio Miami College, now the University of Cincinnati. In the Cincinnati Hospital he took an unusually active part in the contagious diseases department. His students speak of him as one who "won a lasting place in their hearts," and the Medical and Surgical Staff of the Bethesda Hospital, of which he was a member, declare "His high medical attainments have always been recognized." They also pay a tribute to his "courteous, genial and modest personality." The faculty of the University of Cincinnati College of Medicine records that "he was one of its most loyal, farseeing, and honest members," and that "he was a man of rare scientific attainments and most modest demeanor"; and it asserts, what every one who was in professional touch with him will endorse, that "he possessed an intimate knowledge of pharmacy, chemistry, and medicine," such as made his death "an almost irreparable loss." While his associates respected him for his scrupulous and strictly scientific judgment, his patients esteemed him because of his transparent honesty and unswerving loyalty. He had rare acumen and diagnostic and therapeutic ability of a high order, and these he placed at the service not only of his patients but of his colleagues with a splendid liberality.

As a man and a friend he is gratefully remembered. His tender and sympathetic nature sweetened his manly character and held those who knew him best in genuine fellowship. He possessed an analytic mind which faced the problems of social and public life with the same penetration as that by which he solved the problems of his chosen science, and he devoted himself to every allotted task with the unflagging energy with which he carved his career to professional eminence and public affection.

In addition to being a thoroughly scientific man and an excellent physician, he was also a humanitarian. The needy had a good friend in him, and the memory of his personal influence and help lingers on in many hearts and lives. His was a life of many-sided usefulness, and the Cincinnati community will long cherish it as one of signal merit.

Pyocyaneus Meningitis in the Course of Tetanus.—Chauffard and Laroche report the case of a patient whose tetanus was improving under intensive serotherapy when a meningitis set in. The *B. pyocyaneus* was found in the spinal punctate, having doubtless been introduced by an unclean needle while injecting serum into the spine. The complication responded to urotropine treatment and patient recovered.—*La Presse Médicale.*

Therapeutic Hints.

Muscular Rheumatism.—The following formulæ, though not new, produce marked relief from pain in this condition:

℞ Olei gaultheriæ.
Olei gossypii seminis.
Linimenti saponis.
Tincturæ aconiti.
Tincturæ opii, aa.....cc. 20.0.
M. Sig.: Liniment.

℞ Tincturæ iodi.
Aquæ ammonii.
Chloroformi.
Tinctureæ aconiti, aa.....c.c. 30.0.
Linimenti saponis, q. s. ad.....c.c. 700.0.
M. Sig.: External use.

℞ Olei gaultheriæ.....c.c. 8.0.
Liquoris potassi.....c.c. 44.0.
Mucilaginis acaciæ.
Glycerini, aa.....c.c. 16.0.
Aquæ destillatæ, ad.....c.c. 250.0.

M. Sig.: One teaspoonful every three or four hours.—*Medical Fortnightly.*

Enemas.—The following formulæ for enemas may be used for different degrees of acute and chronic constipation:

℞ Ox gall.....gr. xx.
Glycerin .....℥j.
Starch water.....0j.

℞ Infusion senna compound.....℥viii.
Water, q. s. ad.....0j.

℞ Emulsion asafetida.....℥viii.
Powdered tragacanth.....℥iv.
Water, q. s. ad.....0j.

℞ Castor oil.....℥ij.
Gum arabic.....℥ss.
Water .....0j.

℞ Spts. turpentine.....℥ss.
Gum arabic.....℥ss.
Water .....0j.

℞ Glycerin .....℥ij.
Water .....0j.

℞ Magnesium sulphate.....℥ij.
Water .....0j.

Normal salt solution is the simplest and one of the most efficacious enemas; this, with the last two formulæ given, should be injected at a temperature of 102° Fahr.

Simple Means to Eradicate Flies.—A small quantity of oil of lavender (five cents' worth) mixed with the same amount of water and sprayed from a common glass atomizer in places where flies collect will drive them away. Sprayed around the dining room and on the table linen it refreshes the majority of people but is obnoxious to flies. Likewise geranium, mignonette, heliotrope, white clover, honeysuckle and hop blossom odors will remove these pests. A French scientist has stated that flies have an intense dislike for the color blue; rooms decorated in this color will help to keep them out. Another mixture helpful in their removal is one tablespoonful of cream, one of black pepper and one of brown sugar; put in a saucer, darken the room except one window and in that place the saucer. Burning pyrethum powder stupefies the flies, which must be swept up and burned.—*Merchants' Association of New York.*

Military Medicine.

LETTERS FROM AN M. M. R. C.

It is most advisable for the doctor expecting to join the ranks of the M. R. C. to take into serious consideration Bulletin VII of The Army Service School which gives general information for officers entering service in Medical Reserve Corps. You may likely be told at your academy of medicine or wherever else you have enrolled, that you need pay no attention to the necessities the Government has recommended you to provide yourself with. This is a mistake and the depressing advice was intended more for those men who intended buying or had already bought their mounted equipment from saddle cloth to horse shoes. The latter of course is quite unnecessary. An officer in a training camp is in no wise different from a private. The Government has no intention of furnishing him with a horse, even if it had the horses (which it has not). You may be told at the station where you enlist that you will be able to purchase the requisites at the quartermaster's at cost price. This at the present moment is an exaggeration which will lead to great personal discomfort.

The following is the list of articles required by General Orders No. 39 not optional:

Equipment A.—(*a*) 1 mosquito bar; (*b*) 1 basin, canvas; (*c*) 1 bedding roll; (*d*) 2 blankets; (*e*) 1 bucket, canvas.

To an officer coming to a training camp, the only absolute requisites are the bedding rolls (*c*) and the blankets (*d*). He may be able to buy the blankets from the Quartermaster Department of his post, but it is most unlikely that he can procure the bedding roll at the present time. The bedding roll is an absolute necessity. As soon as he is finished sleeping the bed clothes and pillow are rolled back so they occupy one-third of his cot. The barracks provided at these training camps are very dusty and if bedclothes and mattress were not protected by this bedding roll they would soon become filthy. The cost of a good canvas bedding roll is about $11. In travelling, the folding cot and chair are placed in the center of this roll. The other articles on this list are only essential to those men who have to sleep in tents. In all the encampments for the training of medical officers there are lavatories, so the buckets, basins, etc., are unnecessary and need not be procured till the time comes for them to be ordered away at the completion of their course.

Under the list of clothing is the following which is not optional: (*a*) 1 belt, waist; (*b*) 2 breeches; (*c*) 1 gloves; (*d*) 4 drawers, pair; (*e*) 2 laces, shoe, extra pair; (*f*) 2 shirts, flannel, O. D. (olive drab); (*h*) 2 shoes, marching pair; (*i*) 6 stockings, pair; (*j*) 1 tag, identification; (*k*) 4 undershirts; (*l*) 1 clothing roll; (*m*) 1 cot; (*n*) 1 lantern; (*o*) 1 locker-trunk; (*p*) 1 slicker.

Starting at the top—the belt has to be of regulation material (an O. D. woven cord cloth). These can always be procured at the quartermaster's for a few cents. Leather belts are not permitted. When it comes to breeches 3 pairs khaki are better than 2 pairs. You will find that they get very dirty and will have one pair in the wash every week. Any other variety of cloth except khaki is not used in training camp. This really applies to your entire dress uniform. It will practically be of no use to you after you arrive in training camp. You are not permitted to wear it except in travelling. It is really foolish for a man who is considering dollars and cents to go to the outlay of an expensive uniform. The inexpensive khaki is not only quite proper but is better suited to conditions. The Quartermaster is usually out of the sizes you wish both in breeches and coat or blouse as it is called. You can always procure these at the Post Canteen however, at an advanced price. A pair of breeches that can be bought for a little over $2 at the Quartermaster's will cost you $6.50 at the Post Canteen or army and navy supply stores found in most cities. Even this is much better than buying your outfit from an expensive tailor. Buying khaki uniforms at such places is money absolutely thrown away. Remember that they all have to suffer at the hands of indifferent washwomen. Both coat and trousers are needed by you as soon as you join your training camp. Gloves (*c*) are of no value to you in camp. Shirts (*f*) can be procured from your Quartermaster only occasionally in the size that you require. Provide yourself with at least two before you come into camp. If you can buy them at the Quartermaster's they will cost you only $2. If not found there you can always get them at the Post Canteen for $4.50. When it comes to shoes (*h*) you will find that the ordinary shoes that you are accustomed to wear, are quite unsuitable for marching. The regulation shoe when it can be procured at the Quartermaster's will cost you $2.11. The chances are that you will find none of your size at this source. Again you can always get them at the Post Canteen, and the shoe will cost you $6.50. It is most advisable to get your shoes hob nailed. It will keep you from slipping and make your drills and hikes much easier. The proper care of the feet is a most essential thing in this life of intensive physical training. The Quartermaster can always furnish you with a cot, also a mattress and pillow if you so desire. It is best to buy these things on your arrival at the post. Incidentally it might be well here to mention that all these things must be cash purchases. Credit is not given the new enlisted man, and under this heading the M. R. C. man comes. A portable small electric light (*n*) is a good thing to have. Often thunderstorms will put the electric lights of your barrack out of commission and getting your bed and self ready in the dark is not much fun. It is doubtful whether you can procure a locker or trunk (*o*) from the Quartermaster. The same varying degree in price exists and you can buy a good one at the Post Canteen for $12. This trunk has to be of regulation size and color. It occupies a certain space at the foot of your cot; in the same way in transit, the baggage car or ambulance accommodates a certain number of a certain size. They do not care for odd sizes and shapes. Most trunk houses will know what the regulation trunk is. The last on this list is the rain coat (*p*). Anything will do to bring with you. By keeping a sharp eye open on the Quartermaster Department you will sooner or later get the proper thing.

The toilet articles mentioned among those required are all necessary and should be with you when you arrive. It would be well to remember some talcum powder for your feet and some sooth-

ing ointment for pruritus ani. The remaining articles on the list will not be needed at once in training camp and can best be purchased from the Quartermaster when the time comes that you need them.

Do not buy cheap puttees. Imitation pigskin will part after the first tough drill. In the same way do not buy a cheap service hat—the cap worn with dress uniform will never be worn by you here. Do not go to fancy light shades of pearl gray or green felt. Take the regulation brown and be prepared to pay $6 for it.

To the casual reader of this rather dry account of needed expenditures by one becoming an officer of the Medical Reserve, the question must have already arisen, "how is it that the Government Quartermaster is short of these necessities, yet the Post Canteen is well provided?" It is a question I cannot answer. I am rather inclined to the belief that the Quartermaster Department is not always out of the supplies that it claims it is out of, that a full stock of everything is on hand but is held in readiness to provide for the wants of the new private recruits who enter the army practically naked and bare. An officer is always supposed to furnish his own uniform. At the present time there is no vital reason why they should assist the officer of the M. R. C. at their own inconvenience, to procure their outfit at cost prices. The attitude of the regular army at the present moment toward all reserve corps men is comparable to the toleration of the fox terrier for the family cat. There is a natural rankle in the breast of the man who has been in the service fifteen years before the grade of major was reached, against the M. R. C. who obtained his rank of major from Washington last month, and I doubt if this feeling will ever be entirely overcome.

TUBERCULOUS SUSPECTS IN THE FRENCH ARMY.

SINCE laboratory tests and physical examinations seem inadequate to detect the presence of pretuberculosis and the incipient stage of the disease, some authorities advocate a dependence upon the rational signs of evening fever and tachycardia in addition to others somewhat less significant, such as unmotivated cough and loss of weight and appetite. This point of view is found among certain sanatorium practitioners and it will be of interest to compare it with the conclusions of military practitioners who have to evacuate from the ranks soldiers who probably are about to develop the disease or are already attacked. Where there is selection to be practised among hundreds of men certain pseudotuberculoses confuse the subject, and practical criteria are in urgent demand. In an article by Professor Sergent abstracted in the *Revue de médecine et de chirurgie pratiques* for July 25, the statement is made that 50 per cent. of suspects are able to remain among the effective troops. Either they have or do not have the disease, but even when they have it it is as a rule not an incipient but an extinct or stationary type of the disease. Among the spurious suspects we find tuberculophobes and malingerers, dyspeptics, and psychasthenics and subjects with old intranasal and bronchial lesions.

A pulmonary tuberculosis in earlier evolution is most commonly suspicious through the presence of emaciation, weakness, anemia, dyspepsia, and fever. The physician, as a rule, is overinclined to suspect the presence of early progressive tuberculosis and is deceived by the malingerer, the poorly nourished man, and even the old rachitic subject. Some in these classes will very likely die of tubercle at some period more or less remote. The flabbiness and weakness of the hypotonic subject and psychasthenic may deceive the unwary. Anemia and dyspepsia prevail extensively under the most varied conditions, and some of these subjects may have slight rises in evening temperature, due occasionally to chronic appendicitis. "Suspicious bronchitis" is a term in common clinical usage and is often of intranasal or intrapharyngeal origin. One must never forget that among these bronchitics there may occur cardiac and nephritic subjects.

In the suspect who coughs one must always investigate thoroughly the state of the upper air and food passages. During the present war French authors have again and again called attention to false tuberculosis of intranasal origin. Trench life is especially calculated to cause a respiratory syndrome. This is a tracheobronchitis accompanied by sweating feet and a stopped nose. In not one case has this affection passed into tuberculosis. Then there is the secondary bronchitis from gassing. Of 300 of such cases Sergent has not seen a single one of supervention of tuberculosis. The terms pseudotuberculosis and tuberculous suspect, he says, do not reflect much credit on the profession and should be done away with.

Neurasthenia in Soldiers of the Home Forces.—A report of this condition and its effects has been made to the Medical Research Committee by F. W. Burton-Fanning and published in a recent issue of *The Lancet* (June 16). The term neurasthenia he uses in its widest sense to include disorders of the nervous system which are believed to have no organic basis. The fact of the frequency with which neurasthenia underlies patients' maladies in civil practice and the unawareness of either them or their doctors of the true explanation of the symptoms even while the patients are at work hampers diagnosis. Fanning was therefore not prepared for the astounding prevalence of neurasthenia in the occupants of beds in a military hospital. The country, he considers, is suffering an enormous loss of man power on this account, aside from the great expense, the occupation of beds by these men, and the moral and physical deterioration of the patient. Numbers of his patients have spent far more time in hospitals and convalescent homes than with their units. To a large extent he believes these losses could be prevented.

During ten months Fanning had charge of a number of medical beds in the First Eastern General Hospital, Cambridge, which had carried from time to time between 120 to 180. Into these beds 2,240 patients were admitted during his service, of whom 640 came in convoys from overseas and the remaining 1,600 were from Home Forces. Out of the last number he found 509 to be suffering from neurasthenia and to be free from any organic dis-

ease, averaging about one-third of the admissions into medical wards from Home Forces from neurasthenia. A large proportion of them realized that they were of a nervous temperament, and that this constituted their disability. A larger number were more or less ready to admit that they were nervous, but had not connected their supposed malady with this nervousness. The remainder of the patients were unwilling to believe that their symptoms were not caused by disease of an organ, and they would not allow that their nerves had troubled them. With a few exceptions, they were sure of their unfitness for military service and did not conceal their resentment at being called up.

Fanning gives a picture of the neurasthenic from boyhood on, showing the existence always of a nervous temperament. The patient is often an only son with bad parental training. Later trials have not been met philosophically, and the mind is constantly occupied with disquieting thoughts. The nervous system becomes overwrought and oversensitive, and thus the working of the whole economy is deranged. A very small proportion of these patients had enlisted voluntarily. Before the date of compulsory service there was seen in this hospital nothing to compare with the recent outbreak of neurasthenia. Their heart and soul are not in their service, they dislike the work, and find their companions uncongenial.

While the symptoms are never confined to any one region, weakness, prostration, a feeling of exhaustion, or sudden collapse are invariable, and Fanning states that our minds must be at peace if we are to possess energy and *joie de vivre*. This these neurasthenics lack. Rheumatism is the most common avowed cause of disability, especially acute rheumatism. However, disquietude of mind is by far the most common cause of headache and backache. When complaint of the limbs is made it will often be found that the subjects of these painful limbs have long been of neurotic temperament, and the trial of a long march concentrates their attention on their limbs and increases their so-called rheumatism. Gastritis is another complaint particularly affected by these patients. The heart, according to Fanning, is the seat of some sensations in all neurasthenics, whatever may be the main complaint. Practically every other organ may receive its share of attention as a seat of trouble for these neurasthenic men.

In discussing means of prevention, Fanning considers that in general the prevention of neurasthenia comes within the sphere of education. The atmosphere of the English public school seems to be one means to prevent neurasthenia. Sedentary occupations seem to have a tendency to increase the condition. Recruits would show fewer breakdowns if they could be better classified and gradually got on full drill. It is everything with these men to establish self confidence. Again when the case comes to court, the physician should be able to make a proper diagnosis of the case and thus assure the patient of the safety of his condition and administer sufficient reassurance to aid in recovery.

The treatment resolves itself into an attempt to remove from the patient's mind whatever is the disturbing influence. The patient's confidence must first be gained by the physician; a careful physical examination should be made, with explanation of supposed symptoms. Occupation is much better than rest, and Fanning had the men put to marches as soon as they were able.

He does not consider that real fighters can ever be made of the majority of these neurasthenics, although a small proportion may return for service. The neurasthenic cannot be fired with the spirit required in attack or with the willingness to make the supreme sacrifice. But he concludes that there should be plenty of work at home or behind the line of which they are quite capable and which, after a little treatment perhaps, they would perform efficiently.

Casualty Surgeons Wanted.—The Council of National Defense, through the general medical board has sent a letter to the heads of various hospital staffs asking them to submit the names of surgeons on their staffs who are specializing in brain surgery or who are casualty surgeons of large experience.

Surgeon General Amends Rules Governing Physical Examinations.—The Surgeon General of the Army has amended the regulations governing physical examinations of men called by the local boards so as to authorize the acceptance of men 61 inches high, weighing not less than 110 pounds; 62 inches, same weight; 63 inches, not less than 112 pounds. The Surgeon General also authorizes the acceptance of men 64 inches high and over if less than standard weight, provided under weight is due to temporary causes, and can, in the opinion of the medical examiner, be reasonably explained.

Sanitary Conditions at Camps to be Investigated.—An announcement from the Surgeon General's Office states that Colonel H. C. Fisher has left Washington for a sanitary inspection of the cantonments in the southeastern department, including the States of North Carolina, South Carolina, Alabama, Mississippi, Tennessee, Louisiana, and Arkansas. The plan is to have general sanitary inspectors attached to the Surgeon General's Office who shall make careful inspections of all cantonments in order that he may know at first hand the actual conditions and take timely steps to remedy any defects in sanitation.

Hookworm Among Troops.—Discovery of hookworm infection in forty-seven out of seventy-five militia recently mobilized for war service and suspected of shirking duty, has caused the Public Health Service authorities to recommend prompt examination of all units of the National Guard and National Army at present organized, especially those from the warmer parts of the country. This discovery of hookworm was made by Dr. C. Wardell Stiles of the Public Health Service at a Government reservation in connection with certain experimental work that was being carried on.

School for Training Crippled and Blind.—New York is to have a Red Cross Institute for the purpose of teaching crippled and blind men to be self-supporting. Jeremiah Milbank has contributed $50,000 for the promotion of this philanthropy and Dr. Edward Devine, director of the New York School of Philanthropy, has sailed for France to study the methods of teaching the crippled and blind that are now being used in the reeducational schools of that country.

Another Hospital Raided by German Airmen.—A cablegram to the Associated Press describes an infamous night raid made by German airmen on the hospital at Vadelaincourt. Five bombs were deliberately dropped on the buildings. Two of these did serious damage, one falling on a shed occupied by wounded soldiers and the other on a dressing station. One man nurse, one woman nurse, and ten wounded men were killed in the hospital proper. At the same time four bombs were dropped on the Evacuation Hospital, killing eighteen men nurses and wounding forty-nine. At about the same time a German aviator attacked the hospital at Chateau Mont Hairons. The bomb exploded in a ward filled with wounded men, killing one of them. Ten wounded soldiers were killed on the same evening at Berupt by a German shell. Proof of premeditation on the part of the German authorities in making these attacks was furnished by a photograph found on a German aviator brought down at Dead Man Hill. The photograph represented the Vadelaincourt Hospital, with the red cross sign indicated clearly.

Recruiting Nurses for Emergency Service.—Members of the Mayor's Committee of Women on National Defense of New York are urging young women to adopt nursing as a profession. They are sending out large numbers of letters setting forth the advantages and requirements of this profession to recent graduates of high and private schools. It is hoped in this way to get young recruits who can be trained to fill the emergency at home while the graduate and registered nurses are serving with the armies abroad.

The Need of Specialized Surgery to Meet the Physical Disasters of War.—The Surgeon General has authorized the following statement in justification of the formation of the highly specialized surgical units, as surgery of the brain, surgery of the ear, nose, and throat, and surgery of the mouth. This highly specialized work lends to the department of general surgery, of general medicine, and of neurology a refinement and precision of diagnosis which in many problems is the essential forerunner of satisfying medicinal and operative therapeutic results. The vital necessity of ophthalmoscopic examination by the ophthalmologist in the work of the brain surgeon; the need of prompt release by the brain surgeon of increased intracranial pressure to save eyesight; the value of expert examination of the ears by trained otologist in the elucidation of the problems of neurology and cerebral surgery; the need of search by the expert rhinologist and oral surgeon for foci of infection in the accessory sinuses; the tonsillar tissues and the dental areas, are so well known that it is useless to elaborate the catalogue or further emphasize the facts. For years this type of specialized and expert work has been at the disposal of the practice of medicine in civil life; for the first time in history it has become an integral part of the practice of military medicine and surgery. Such specialized surgery may proceed along three lines:

1. Immediate service, or what is ordinarily known as first aid, to be given at the first dressing station. Time is of vital importance in dealing with many head injuries, involving lesions of its special organs, notably of the eye, and many eyes have been saved which otherwise would have been lost where it has been possible to act at once. As to the accuracy of this statement, all eye surgeons who have been at the front will testify.

2. Later service in the base hospital where all operative procedures of these types of special surgery can be brought into deliberate action. The triumphs of oral surgery in particular are matters of common knowledge and of scientific record, and the same is true of the procedures of cerebral surgery and of those of the eye and ear.

3. Final service in special hospitals devoted to reconstruction and reeducation. In such hospitals the work of the department of the surgery of the head will find and has found one of its widest and most important fields of action, not only in individual work but in the work devoted to those who must be trained for special duties in these regards.

Red Cross Appropriations.—The American Red Cross announces that its war council has appropriated $100,000 for medical research work in France. This action followed a report from Major Grayson M. P. Murphy containing the following: "An extraordinary opportunity presents itself here for medical research work. We have, serving with various American units, some of the ablest doctors and surgeons in the United States. Many of these men are already conducting courses of investigation which if carried to successful conclusions will result in the discovery of treatments and methods of operation which will be of great use not only in this war but, possibly, for years afterwards. To carry on their work they need certain special equipment. At present, equipment and personnel can not be obtained through ordinary Government sources without delay, which makes this source of supply quite impracticable."

Columbia War Hospital No. 1.—Columbia Hospital, New York City, which was accepted as a war hospital by the Government some time ago, was designated as United States Army General Hospital No. 1 in army orders published. It will be one of a series of big hospitals where serious cases requiring long treatment will be taken.

Rockefeller Foundation Increases Gifts to War Relief Work.—Announcement has been made that besides applying the income from the $100,000,000 given the Foundation by John D. Rockefeller to war relief work, the principal will be drawn upon this year to the extent of $10,000,000. Already appropriations aggregating $6,426,872 have been made from this draft upon the Foundation's investments. They include $5,000,000 given the Red Cross, $340,000 for work about the training camps for American soldiers, $402,500 for medical research in the mobile hospital in France, to the National Committee on Mental Hygiene, and to the Rockefeller Institute for Medical Research. A fund of $300,000 was also set aside to build and equip the hospital, under the control of Dr. Carrel, to teach new methods of war surgery. A number of relief associations have also received large sums.

Judge Robert S. Lovett has resigned as chairman on cooperation of the Red Cross by reason of his appointment by President Wilson to membership on the war industries board. Mr. C. A. Coffin has been appointed to succeed Judge Lovett.

MEDICAL RECORD.

THE THREATENING MEDICAL FAMINE.

THE Mayor's Committee on Hospital and Medical Facilities states that unless the War Department speedily announces a program for such disposition of drafted hospital interns and medical students as will meet the needs of the army and of the civil population an appeal will be made to Congress for appropriate legislation. The urgency of the situation has again been brought to the notice of President Wilson and Secretary Baker, and it is hoped that an executive order to relieve the situation will be issued soon.

The contention of the Provost Marshal General that the draft would not make serious inroads on the medical schools is refuted by returns received by the committee directly from twenty medical colleges. The following figures, showing the percentage of medical students drafted and accepted under the first call, have been given out by Dr. S. S. Goldwater, chairman of the committee: University of Nebraska, 34; University of Cincinnati, 32; Western Reserve University, 31; Atlanta Medical College, 17; Hahnemann Medical College, Chicago, 22; University of Wisconsin, 20; Columbia University, 30; University and Bellevue Hospital Medical College, 22; Cornell University, 21; University of Virginia, 9; New York Homeopathic Medical College, 33; Syracuse University, 29; Medical College of South Carolina, 18; University of Michigan, 23; Jefferson Medical College, 22; Marquette University, 20. In some instances these figures refer to the graduating class only; in other instances they include the total student body.

But this is not all. The hospitals are suffering acutely through the drafting of their interns. The Mayor's Committee publishes letters from the Johns Hopkins Hospital, the Mary Immaculate Hospital, Jamaica, L. I., the University of Wisconsin, and several of the hospitals in Chicago, all testifying to the crippling of their work by the loss of their house doctors. Men needed on the farms and in workshops are exempted, although a shortage in these branches of industry could be made up at very short notice. A physician, however, takes five or six years in the making, and if 25 to 30 per cent. of the students and hospital interns are taken in the first draft, and as many more in each subsequent one, the medical famine will soon be acute, and when it comes it will be irremediable.

POST GONORRHEAL NEUROSES.

THE recently published work on gonorrhea by Carle is said to contain a novel chapter on this subject, an abstract of it being found in the *Revue de médecine et de chirurgie pratiques* for July 25. The mechanism of these cases is not always the same but there is always the neuropathic predisposition and the possibility of cure by rest, change of scene or occupation, or marriage. The morale of the patient may be profoundly upset, so that he may give up his occupation or take some other radical step. Suicide sometimes results. Whatever treatment is used doubtless cures by suggestion in part. The patient is usually distressed by one or two particular symptoms, such as the expressed morning drop or by subjective sensations. He often believes he has a stricture when none is present. The best treatment, in as far as it helps by suggestion is scientifically wrong. Thus while experts no longer give copaiba, as being both inert and irritating, this medication is often welcome to the patient who may think it good for his kidneys. In other words it is well to cater to the empirical and the popular. Patients have always used balsamics and have at least believed that they were benefited thereby. Even in the absence of stricture it may be well to allow the patient to believe the contrary and then pass the cold sound. If the urethra is the seat of paresthesiæ it may be well to instill a little cocaine. If the patient wants injections even although the discharge comes from the lacunæ of the urethra beyond their reach, let him have them.

As for the constitutional treatment our opportunities are equally great. The patient no doubt benefits in the two fold way from a remedy like strychnine. Bromides do harm and the cold douche is not a good suggestive remedy nor in fact is anything of a shock nature. These patients are to be regarded as pseudoneurasthenics and it is a great blunder to condemn them to a rest and isolation cure when they need diversion. Left to themselves on a farm they become introspective to the last degree. After a brief interval of change from their routine their morale is best assured by a return to their regular activities. As they have often been dieting themselves with painful precision it is well to have them return to liberal regimen. The practice of the physician to insist on a rigid and literal carrying out of orders had best be slurred over for these patients are naturally contrary and impatient. While these affections are by no means imaginary it is difficult to make an absolute diagnosis. Some one or more organs are at fault, perhaps not in the genital sphere at all—for example there may be a demonstrable disorder of the stomach, or instead of a disturbance of some organ the entire trouble may be traceable to marital in-

compatibility. In other words in the worst of these cases the gonorrhea only serves to focus a general malady.

THE THERAPEUTIC USES OF GARLIC.

JUST at the time of the outbreak of the present war the Allies had been pretty well schooled to the belief, through the success of the German pharmaceutical houses, that the synthetic compounds were the all-powerful remedies in their therapeutic action on the commonly encountered diseases of today. The vegetable compounds bade fair to disappear from the white light of popular medical favor.

Now all is changing. For the past three years the American pharmaceutical houses have cleverly taken up the manufacture of some of these synthetic drugs, and produced good ones. However, the temporary scarcity of some and the lack even yet of others together with the increased price of all, have caused a sense of general dissatisfaction among the members of the medical profession. A realization, too, of the ignominiousness of our former dependence upon the German patented chemicals has awakened a desire for a return to nature's products when possible. Thus are the vegetable drugs again coming into their own. Among these garlic, *Allium sativum*, seems to be swinging into therapeutic favor. It comes with no surprise, for garlic is one of the oldest of the vegetable drugs and long-tried in the hands of both the profession and the laity. While its popularity with physicians declined in favor of the newer treatments, old women in out-of-the-way villages have gone quietly on applying the juice of garlic and onions in the home treatment of whooping cough, typhoid fever, pneumonias, and diphtheria with marked success.

Probably few vegetable remedies have been credited with a wider range of therapeutic value. William Charles Minchin writing in the *Medical Press and Circular* for June 13, 1917, gives the results of years of special study of the therapeutic action of oil of garlic. This oil is composed of allyl sulphide with volatile terpenes, and would appear to be Nature's antiseptic for internal use, destroying many pathogenic germs within the body, and being at the same time harmless to the tissues. In this respect it seems to differ from every other known antiseptic of any great value. Its germicidal power outside the body, compared with that of carbolic acid or other toxic substance, does not seem to be very great, but the body tissues may be saturated with oil of garlic for a considerable period of time, even continually, without injury to them. The oil appears to be so volatile that it may be beneficially used by inhalation in pulmonary conditions; and when applied locally to any part of the skin, it readily penetrates to the deepest tissues in the region of the application, reaching even the bones, and finds its way into the blood current so that its odor can be detected in the breath in from ten to fifteen minutes after the application to the skin. According to Minchin, it destroys the germs of many infectious diseases, as typhus, typhoid, and diphtheria. When typhus or typhoid fever has become established in the body, he recommends the use of one dram of succus allii sativi every four to six hours, in beef tea or with syrup. In typhoid, if given early, he says it has a definite abortive action, but is beneficial at any stage of the disease.

In diphtheria garlic is to be applied with but little dilution. It is necessary to keep it in the mouth constantly for several hours so that it may act as a local application to the throat and surrounding tissues. The exact amount used is not so important as is the constant application of it to the tissues where it is needed. The simplest way, Minchin says, is to have the patient keep a clove of garlic in the mouth and occasionally crush it between the teeth, thus expressing the juice. This may be kept up indefinitely. In three or four hours, from one to two ounces may be used in this way. At the expiration of this time, one not infrequently finds that all membrane has been removed from the tonsils, and the temperature has fallen even to normal. This treatment is also beneficial, according to Minchin, in those cases which have been too late for serum to be of use. A continuation of this method of treatment carries on the beneficial action and while one or two ounces a day is sufficient, an overdose cannot be taken. The patient suffering from diphtheria neither smells nor tastes garlic, but merely finds it hot.

In the treatment of whooping cough Minchin has found garlic to be most efficacious. In the cases of adults an inhalation of the fresh succus allii sativi, rapidly relieves the distressing symptoms. It must be used, however, continuously from three to five hours for two or three days in order to produce the best results. In the case of infants and young children 20 minims to half a dram of the juice of the garlic taken internally every four hours in a little syrup gives speedy relief in the early stages. The author lays special emphasis upon the beneficial effects of garlic in the treatment of tuberculosis, and he quotes the results obtained by the staff of the Metropolitan Hospital, New York, in the treatment of 1082 cases of tuberculosis according to fifty-six different methods, out of which garlic gave the best results.

These are only a few of the conditions in which Minchin says garlic has been used with strikingly beneficial results; it has been recommended as a stimulating expectorant, anthelmintic, and antispasmodic, and as an effective detergent of foul ulcers and sloughing wounds—indeed so nearly a panacea does it seem to be that one's scepticism is necessarily aroused. Nevertheless it is worthy of a trial, and perhaps if its virtues should prove to be real some pharmaceutical chemist may devise a method, in the interests of the bystander, of suppressing the odor without weakening the therapeutic efficacy.

One interesting observation is alluded to by Minchin, who says that some years ago the health officer of Croatia ventured the opinion that the well-

known longevity of the non-combatant portion of Bulgaria's population was due to their ingestion of large quantities of garlic, and not, as Metchnikoff assumed, to their use of sour milk and its products. Against this, however, is the fact that other alliophagists, who know not the Bulgarian bacillus, Spaniards for example, attain to no unusual length of years.

Relation of Industrial Unrest to Alcohol

Industrial unrest which exists to a greater or lesser extent in all parts of the world is of especially serious import in the present crisis, and anything tending to abate it must be welcomed. In the *Lancet* for July 28, 1917, A. F. Stanley Kent has a paper in which he points out the connection between industrial fatigue and alcohol, and incidentally the relation of industrial unrest to alcohol. Industrial fatigue is brought about by the conditions of labor, long hours of monotonous work, frequently performed in unhygienic and uninteresting environment. The workers are often underfed while their ambitions and aspirations have been so blunted that they frequently more nearly resemble mere machines than human beings. Moreover, this is not all with which the factory worker has to contend. His home is in too many instances so squalid and wretched that he has nothing to look forward to but a dreary round of tiresome labor. Industrial fatigue is therefore apt to culminate in a feeling of utter helplessness and hopelessness. The human machine, in order to work harmoniously and efficiently, must have suitable surroundings. In America and in Canada the fact has been recognized, and by many employers every effort has been made to insure to the worker satisfactory home and factory conditions. In many cases, to the honor of mankind be it said, this has been done as much on the grounds of humanity as because such a policy pays. Consequently, it may be said that a good deal of the industrial unrest, which is a menace to the well-being of European nations and, in a lesser degree, to the countries on this side of the Atlantic, is largely due to the conditions under which so much industry is carried on. The conditions of labor induce industrial fatigue, which induce physical discomfort. The discomfort can be diminished by drink, and therefore the worker drinks. Because the effect is transitory the dose will be repeated again and again, and industrial alcoholism will be established. Industrial alcoholism aggravates industrial unrest, caused, in the first instance, by industrial fatigue. Therefore, as industrial fatigue and industrial unrest are related as cause and effect, the remedy lies in lessening industrial fatigue. For example, the hours of labor can be shortened, for the result of so doing is beneficial to output. Housing conditions should be improved, and factory environment bettered so that the worker should not be deprived of all pleasure in life. The true cure for alcoholism, industrial fatigue, and unrest is the provision of decent surroundings in the factory and in the home, adequate wages, leisure, and relaxation. By such means ambition will be stirred and the worker will soon regard himself as an important unit in the scheme of life, and one whose self-respect and usefulness must not be impaired by drink.

Gonorrheal Meningitis.

It has doubtless occurred to more than one military surgeon that some of the alleged cases of cerebrospinal meningitis in young soldiers could have been due to the gonococcus, especially if the patient had a urethral discharge at the time. The close resemblance which obtains between the meningococcus and gonococcus lends some plausibility to the view that under certain unknown conditions the latter which sometimes does attack the meninges can behave like the former. Such cases are really examples of gonococcus sepsis with exclusive meningeal localization, and are of the same type as typhomeningitis. While cerebrospinal meningitis is sometimes preceded by a bacteriemia, it is usually held to be propagated directly from the rhinopharynx to the encephalon. In a case reported by Blind and Ricard in the *Paris Médical* the diagnosis was made from the presence of the gonococcus in urethral pus and by the meningeal syndrome. The mild type of the disease and the evident absence of cerebrospinal meningitis in the *entourage*, together with the absence of the meningococcus in the lumbar punctate would combine to exclude the more serious disease from consideration. In this case but one spinal puncture was made and there were no cultures nor was an examination made of the secretions of the rhinopharynx. It would seem that in alleged cases of gonococcus meningitis—believed to be a rare affection—all possible control tests should be practised. The bacteriological test of the punctate should be made by an expert owing to the great resemblance between the two forms of coccus. The autonomy of gonococcus meningitis is as yet by no means rigidly proven, and cerebrospinal meningitis may occur in a benign form. In the reported case the withdrawal of but 5 c.c. of spinal fluid caused a notable clinical improvement, and during the present war many cases have yielded to repeated puncture without other treatment.

Complying with the Law.

Some weeks ago we referred to a law passed by the Legislature last winter forbidding the advertising of any agents employed in the treatment of venereal diseases. This law, we have since learned, was introduced at the request of a society having for its aim the suppression of so-called social evils. It was apparently drawn up by someone unused to lawmaking and uninstructed in medicine, and being the work of an amateur was necessarily faulty. It puts an end not only to quack advertisements in the lay press but to reputable announcements of legitimate remedies in the medical press. As in all such cases, the quacks against whom the law is aimed, being ready in the hope of great gain to take big risks, will somehow manage to make themselves and their wares known to the gullible public, while the medical journal, loyally obeying the law, however exacting and unjust its workings out may be, eliminates all forbidden advertisements from its pages. The law goes into effect on September 1, and to-day being September 1, no "advertisement concerning a venereal disease, lost manhood, lost vitality, impotency, sexual weakness, seminal emissions, varicocele, self-abuse, or excessive sexual indulgence" will be found in our pages.

News of the Week.

An Open American University Club in Paris.—For the benefit of college men who are likely to be with the American forces in France, headquarters are to be opened in Paris of the American University Union of Europe, formed recently in consultation with the Washington Government, the American Red Cross, and the International Army and Navy Young Men's Christian Association, by the joint action of about twenty American universities and colleges. It is expected that eventually the union will include most American colleges. The Institute of Technology Club of Paris will merge with the University Union, which will take a hotel or group of hotels to provide at a moderate cost "a home with the privilege of a club for American college men and their friends passing through Paris or on furlough," as the committee explains. The organization also will "aid institutions, parents, or friends in securing information and assist the men in every possible way." The general purpose of the union is "to meet the needs of American university and college men who are in Europe for military or other service in the cause of the Allies."

Sale of Absinthe Forbidden.—Beginning September 1, the sale of absinthe is to be prohibited by the New York City Board of Health, according to the provisions of a section of the Sanitary Code. It will be a violation of the code to "have, sell or offer for sale the alcoholic beverage known as absinthe, a manufactured product containing wormwood, or absinthe, an ingredient which may render the beverage injurious to health."

Death of Two German Chemists.—A press dispatch from Copenhagen, dated August 26, announces that Dr. Eduard Buchner, professor of chemistry at the University of Wurzburg, who was in service at the front as major, has died of wounds. His death followed shortly that of Adolf von Baeyer. Thus two of the greatest German chemists died within a week. Professor Buchner, whose specialty was the chemistry of fermentation, received the Nobel prize for chemistry in 1907.

Commission to Study French Birth Rate.—A commission of American specialists is to make a study of the conditions responsible for the alarming decrease in the birth rate of France during the past year of the war. Dr. J. Morris Slemmons, professor of obstetrics in the Yale Medical School and Mrs. Slemmons, formerly a Johns Hopkins nurse, are on their way to France where they will cooperate with the infant welfare unit now working in France, which is headed by Dr. William Palmer Lucas, professor of Pediatrics of the University of California, and financed by Mrs. William Lowell Putnam of Boston. They intend to review the work already done by French experts and to further elaborate it.

Infant Blindness Increases in England and Wales.—According to the report of the Local Government Board published in the British Medical Journal for the year 1916, there were 7,615 cases of ophthalmia neonatorum in England and Wales, a rate of 9.56 per 1,000 births as compared with 6,806 cases for 1915. Quite contrary to conditions in France, pulmonary and other forms of tuberculosis are showing a decided decrease, the rate being 3.03 per 1,000 population in 1912 as against 2.10 in 1916.

Anthrax Traced to China.—A report of the Local Government Board of England and Wales on an inquiry into several cases of anthrax shows that most of these were cases of external anthrax. In nearly every instance the lesion was situated in the shaving area of the face and neck. Suspicion fell on the shaving brush, and in some of the cheaper brushes examined living anthrax bacilli were found. All the brushes showing anthrax bacilli were traced to a single factory in which Chinese horsehair was used which had not been disinfected before being manufactured into brushes. An investigation is being carried on to determine the precise conditions which must be fulfilled to insure the sterilization of the horsehair.

Ship Carrying Plague Arrives in London.—The British steamship *Mahana*, which arrived at Gravesend from Bombay, on August 13, had on board three convalescent cases of bubonic plague. These were removed to a hospital. During the voyage the vessel had nine cases on board, six of which died. Another case has occurred since the arrival of the ship.

Home for Convalescents.—The Valeria Home for Convalescents, which was founded by the late Jacob Langeloth, has purchased a tract of 550 acres midway between Peekskill and Oscawanna in Westchester County, which will be used as a site for a new building.

Health Department Plans to Treat Drug Habitués.—The New York Health Department announces that plans have been perfected whereby drug addicts wishing to be cured of their habit can apply to the Department of Health for treatment in one of the city institutions.

St. Mary's Free Hospital of New York has received a bequest of $2,000 under the will of the late Mrs. Laura F. Hearn.

Dr. Charles G. Carleton of Lawrence, Mass., was given a testimonial dinner on August 15, in honor of having completed fifty years in the practice of medicine

Infant Mortality in American Cities.—The New York Milk Committee has just made public the results of a study of the infant mortality rates of the cities of the United States. It finds that the death rate among babies in the large cities has been reduced 11 per cent. since 1910. This reduction has been made among cities of 100,000 population and over. The reduction in cities between 50,000 and 100,000 population is only 2 per cent., while those under 50,000 show an increase of 5 pe cent. The general reduction is 9 per cent. The survey covers 150 of the largest cities in the United States, representing one-fourth of the population in the United States. They report 670,000 living births and 68,000 deaths under one year of age for the year 1916, making an infant mortality rate of 100 baby deaths for each 1,000 births reported. The lowest infant death rate in the country, in 1916, among the cities of 100,000 or over, was in Portland, Ore., with a record of only 55 baby deaths per 1,000 births. Fall River, Mass., is the highest with a rate of 163. In the second group, those with a population of 50,000 to 100,000, Hoboken, N. J., has the low rate of 77 against San

Antonio, Tex., which has the high rate of 246. In the cities with populations of 50,000 and under, Brookline, Mass., leads with the remarkably low rate of 32 against Austin, Tex., whose rate was 182. Though there has been a general decrease for all the cities since 1910, the reports for 1916 compared with those of 1915 are not so encouraging In cities of over 100,000 population there was an increase in the number of baby deaths in 1916 of 1,573. Thirteen cities in this group showed reductions, New York City leading with a decrease of 1,048, and infant mortality rate of 93, the lowest in the history of the city. Other cities in this group showing decreases were Philadelphia with a rate of 101; New Orleans, 96; Washington, 105; Jersey City, 102; Rochester, 82; St. Paul, 67; Denver, 84; Portland, 55; Oakland, 65; Scranton, 85; Grand Rapids, 115; Spokane, 57; Albany, 96. The cities in this group showing decreases were: Chicago, 111; St. Louis, 89; Boston, 104; Cleveland, 107; Baltimore, 118; Pittsburgh, 111; Detroit, 112; Buffalo, 113; San Francisco, 79, etc. Of the cities under 50,000 there was an increase of 755 deaths under one year compared with 1915.

The Medical Society of the Missouri Valley will hold its Thirteenth Annual Meeting at Lincoln, Neb., September 20 and 21, 1917, under the presidency of Dr. C. R. Woodson of St. Joseph, Mo.

The National Exposition of Chemical Industries will hold its third annual exhibition at the Grand Central Palace, New York, during the week of September 24, 1917. The exposition will cover all the ramifications of the chemical industry.

The American Association of Orificial Surgeons will hold its annual meeting in Chicago on September 27-29, under the presidency of Dr. B. A. Bullock.

Publicity for City Welfare Work.—The recently organized Committee on Public Welfare has formulated plans for demonstrating to the public through literature, lectures, motion pictures, and tours, an outline of the work performed in the Departments of Charities, Correction, Street Cleaning, Licenses, Health, Police, Tenement Houses, and others. This committee is a non-political and non-sectarian organization which plans to demonstrate how city wards are treated. The committee wishes to focus attention on welfare work in order to insure a continuance and an extension of humanitarian work.

Diet Kitchen Saves Babies.—The New York Diet Kitchen Association has had under its direct care thus far this summer 3,425 babies. Of this number only three have died.

Obituary Notes.—Dr. John Strother Pedleton, for many years a practitioner of medicine at Marion, Va., died in Richmond, on Aug. 14, aged 78 years. He was a graduate of the Medical College of Virginia, in 1861, served as a surgeon in the Confederate Army during the Civil War, and was for many years surgeon at the State prison.

Dr. Harvin C. Moore of Houston, Tex., died following an operation for appendicitis, on August 5, aged 42 years. He was a graduate of Tulane University Medical School in 1898, and an ex-president of the Harris County Medical Society.

Dr. Isadore H. Chicoine, a graduate of Harvard University Medical School in 1894, and for many years a member of the staff of the Lynn Hospital, died after a long illness in that city, on August 8, aged 52 years.

Dr. Homer H. Warner, a graduate of the University of Vermont in 1859, was found dead in his home in New York City on August 10. Dr. Warner was 80 years of age, and served as a surgeon with the First Massachusetts Cavalry during the Civil War.

Dr. John F. Axtell of Newton, N. H., aged 61 years, a graduate of the University of Vermont Medical College, in 1881, died August 10.

Dr. Burdette Ramsey died at Paint Lick, Ky., about August 1. He was a graduate of the University of Louisville in 1853, and at the time of his death was the oldest man in Gerrard County, being 93 years of age.

Dr. William L. Jerkins, a graduate of the Atlanta Medical College in 1903, aged 45 years, died at his home in Moultrie, Ga., on August 8.

Dr. William H. Robertson, a graduate of the Northwestern University Medical School, in 1909, died at his home in Mattoon, Ill., on Aug. 16, aged 43 years.

Dr. Samuel Meyer, a graduate of the University of Louisville Medical School, in 1891, died in the Jewish Hospital of Louisville, Ky., at the age of 48 years.

Dr. John W. Clerke, a graduate of the University of Toronto Faculty of Medicine, in 1884, died at his home in Green Cove Springs, Fla., on Aug. 12, aged 72 years.

Dr. J. Morgan Sims, formerly a practitioner of Collinsville, Ill., died in the Alton State Hospital, on Aug. 16, aged 49 years. Dr. Sims was a graduate of the University of Louisville, Ky., in 1890. He was formerly superintendent of the Arkansas State Asylum for the Insane at Little Rock and later surgeon at the Kentucky Asylum at Lakewood, Ky. More recently he was coroner of Madison County, Ill.

Dr. Kate S. Kavanaugh, a graduate of the Hahnemann Medical College Hospital of Chicago, in 1891, died at her home in Minneapolis, on Aug. 16, aged 63. She practised for a number of years in Menomonie, Wis.

Dr. Thomas E. Callahan of Saguache, a graduate of the Baltimore Medical College, in 1889, died suddenly on Aug. 10.

Dr. Frank S. Bates of Colorado Springs was killed at Fort Riley, Kan., by a stroke of lightning, on Aug. 7. He had just received a commission in the regular army and was to go to Nevada, Mo.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEDICAL REEXAMINATIONS OF RECRUITS—DIMINUTION IN DRUNKENNESS—ELECTION AT THE ROYAL COLLEGE OF SURGEONS.

London, July 28, 1917.

A select committee is investigating the conduct of medical examinations under the Review of Exemptions Act. Surgeon-General Bedford, deputy director of medical services, giving evidence, said the constitution of the traveling medical boards is not

quite the same as that of the ordinary recruiting medical boards; in the former local doctors sometimes assisted and he gave a detailed description of the examination. A recruit had to run the gauntlet of the members of the board, each of whom examined him for a particular form of disability. Then all expressed their opinion, and the president decided what the recruit's category should be; he produced an army instruction that the president must himself classify all recruits. It was remarked that this was a new instruction but General Bedford said it was issued last February. No recruit could be finally rejected without the president's approval. During the year ending on June 30 last, thirty-three boards in the Northern command examined 500,000 recruits. He disagreed with the statement that a successful stock broker with a weak heart might drop down dead in the army through exertion; "that is the very thing he would not do if he were properly classed." He would be put into C3, where he would be as safe as in a church. These are the very men we want—of good education, not fit to go into A1 or B1 but valuable in a hundred offices. He handed in a copy of instructions issued by him in September on the subject of the large number of men found permanently unfit by some boards, emphasizing that every man so found is once and for all lost to military service and cannot again be called upon for reexamination or employed in any military capacity. In future boards must retain every man who is of any potential use whatever in the army. This was decided after a meeting at the war office at which the high percentage of rejections was referred to. General Jenkins, deputy director of medical services, issued an instruction to medical boards in his command to the effect that the large number of rejections left it to be inferred that many men were classed as B3 or C3, or even totally rejected who might be usefully employed on medical service and that there were many duties in the army which incurred no greater fatigue than fell to the same men in civil life; it is to be hoped if the recruiting board realize this there will be a considerable reduction in the proportion of rejected recruits.

Sir Ryland Adkins has given to the select committee on re-examinations his experience as a member of an appeal tribunal. He felt in an increasing degree that the arrangements were not working out in a way to give them the assistance they would like. They were faced with remarkable contrasts in the classification of persons coming before the tribunals. Persons rejected in 1915 and again last year were coming forward classed as A or B1, with a record from private doctors making it very difficult to discern their duty. He thought the difficulty had increased since the passing of the act authorizing reexaminations. We know the doctors are men of ability, devotion, courtesy and good will, but we know too they are understaffed, overworked, and often, if not always, obliged to do things too quickly; so the results at which they arrive are wanting in weight. As to complaints made about tearing up certificates, though the last to believe them all, one could not sit on a tribunal week after week and listen to these stories without concluding there must be something at the base of them. He suggested as one remedy the appointment of certain doctors of 50 years of age or upwards to sit upon the board one or two days a week. Presidents of boards should not have power to overrule the other members. Replying to Sir Godfrey Baring he admitted complaints of examinations being too rapid and cursory had not been without some foundation and men who had been lowered in category should have a right to have their cases reconsidered. How that would be managed during the exigencies of war he did not pretend to show.

Convictions for drunkenness in the scheduled areas of Great Britain continue to decline. In the last four years (to end of May) the total numbers were: 1914—males, 140,133; females, 36,533; total, 176,671. In 1915 the weekly average was 2,517, or a total of 130,884, giving a total of 80,288 in 1916, 1,544; in 1917, 1,039, with a total of but 54,028.

At the Royal College of Surgeons Sir George Henry Makins has been elected president for the ensuing collegiate year. Messrs. Vincent Warren Low and W. Harrison Cripps were reelected and James Sherran elected members of council; Arthur Keith, Jonathan Hutchinson, Tindall Lister, P. Pasley Cole, E. Kenneth Martin and Hildred Carhill, Hunterian professors; F. Gymer Parsons and William Wright, Orris and Gale lecturers; S. G. Shattock, E. Wilson, lecturer. In conjunction with the college of physicians, a number of diplomas in public health were conferred.

OUR LETTER FROM PARIS.

AMERICAN AMBULANCE CEASES TO EXIST—TRENCH FOOT.

(From Our Regular Correspondent.)

PARIS, July 23, 1917.

THE work of the American Ambulance at Neuilly was officially terminated yesterday at half past five o'clock, by Mr. Laurence V. Benét, president of the ambulance committee. At the same time, M. Justin Godart, Under Secretary of State for the Service de Santé, relinquished all claim to the American Ambulance and offered sincere thanks on behalf of the French Government for the magnificent institution, which, he declared, had been a monument to the love and sympathy which the American people bore France during the long months that their Government remained neutral.

No service could have been more touching and impressive, and there were but few dry eyes in the gathering of some two or three hundred Americans when M. Godart, after declaring that the American Ambulance no longer existed, turned to "Monsieur le President" of the dissolved committee and kissed him on both cheeks, the expression in France always of the sincerest thanks.

On Aug. 14, 1914, the Lycée Pasteur was placed at the disposal of the committee forming the American Ambulance, and it was the first hospital formation to commence work in France. It started with 150 beds, which were steadily increased to 600. It organized its own ambulance corps, numbering 170 men and nearly 100 machines.

M. Justin Godart, in closing his remarks, asked that the American flag that had been placed over the entrance door of the hospital on August 14, at its opening, be presented to the Minister of War,

to be placed among the trophies as a lasting remembrance of the great work that had been accomplished. The American Red Cross has taken over the hospital, which will still devote its work to the wounded of the French Army. Dr. de Boucher leaves the hospital entirely, his place being taken by Major Geo. P. Peed of the U. S. Army, and it now becomes American Army Hospital No. 1. The Red Cross has established its headquarters in one of those beautiful monumental buildings facing the Place de la Concorde, where it is now organized, and is rapidly taking over all of the American formations of every kind and sort of benevolent work.

The additional information constantly being brought before us regarding "trench foot" is adding grave importance to this new disease, and forms a warning to army surgeons to treat each and every case with serious attention. In a communication presented to the Société Chirurgicale on July 4, 1917, Dr. Bertrand reported 511 cases coming under his observation, with 60 cases of gangrene, or 12 per cent. Of the 60 cases, 40 were the humid variety and 35 of the cases were bilateral; one case had humid gangrene of the left foot and dry gangrene of the toes of the right foot; one had humid gangrene of the left and dry of the right, and a third case was of the humid variety of both feet and dry of the forefingers of both hands. Five of the cases were attacked with tetanus from ten to twelve days after the onset of the disease, despite antitetanic injections given at the first-aid station and repeated every six days in the base hospital; all 5 suffered a rapid development of the disease and early death.

In two of the 60 cases true gaseous gangrene developed, and one of the patients died. Eighteen of the cases showed gas, but it proved to be due to the mortifying processes in the diseased members. One case succumbed to septicemia. The gravity of the invasion caused the author to amputate in 18 cases, of which 8 were bilateral, and all of these patients survived.

The conclusions of his observations are important, viz., that of the 60 grave cases noted, that which marked their gravity was not the original infection, but what supervened. He therefore esteems it of the highest importance methodically to disinfect the parts affected in a truly surgical manner, as is the rule in all cases menaced by gangrenous invasion, which in these cases should be presupposed.

1. Industrial Benzol Poisoning in Massachusetts. Thomas F. Harrington.
2. Essential Shrinking in the Conjunctiva Occurring in Acute and Chronic Pemphigus, with a Report of Two Cases. Frank A. Conlan.
3. Intestinal Adhesions and Peritoneal Bands in Epilepsy. Heiman Caro.
4. A Comparative Study of Feeble-Mindedness and Psychopathic Personality Among Offenders in Court. V. V. Anderson.
5. Hearing Tests from a Practical Standpoint. George L. Richards.
6. An Epidemic of Dysentery at the Boston State Hospital. Mary Elizabeth Morse.

1. Industrial Benzol Poisoning in Massachusetts.—Thomas F. Harrington reports five cases of benzol poisoning that have been brought to the attention of the Medical Deputy Commissioner of Labor. Of these five cases, three were fatal. All occurred in the auto tire-building department of a rubber establishment in which benzol cement was used. A chemical examination of the benzol used by these men showed that it was free from impurities and of the pure benzol grade. The use of benzol as a cement in the tire-building process was discontinued and naphtha substituted. No further cases of benzol poisoning have occurred since this change was made.

3. Intestinal Ahesions and Peritoneal Bands in Epilepsy.—Heiman Carso first discusses the causes of chronic intestinal stasis; second, the etiological factors present in the causation of intestinal adhesions; third, inasmuch as these bands and adhesions give some evidence of colonic stasis, he makes a comparison of the incidence of this pathological condition as found in the necropsy protocols of an institution for epileptics and in those of a general hospital. A review of 775 necropsy protocols of patients in a general hospital shows a total of 142 intestinal adhesions, while 280 necropsies on epileptics gave a total of 50 showing intestinal adhesions of various kinds. In other words the incidence of intestinal adhesions and peritoneal bands is relatively the same in both series. The writer concludes that, in view of our present knowledge, the constipation of epileptics cannot be said to be due to factors differing far from those usually considered in the colonic stasis of other patients. Intestinal adhesions and peritoneal bands are due to congenital defects, acute inflammatory processes, or mechanical causes. It seems probable that intestinal anomalies are not present in any greater proportion in epileptics than in other persons, and in the last analysis we are still combating, from a therapeutic viewpoint, a general condition, and not one particular lesion or pathological phase of metabolism.

6. An Epidemic of Dysentery at the Boston State Hospital, due to a Member of the Paratyphoid Enteritis Group.—Mary Elizabeth Morse presents a study with reference to the leucocytic reaction in cases of the above mentioned type, some of which received therapeutic doses of vaccine. Comparisons were made with a series of persons who had neither the disease nor the prophylactic treatment, and with those who had had the disease from nine to seventeen months previously. The leucocytic reaction consisted of a hyperleucocytosis, with the highest count rising but little above twice that of the normal count for the individual and a relative increase in polynuclears at one or more periods during the following twenty-four hours after the administration of the vaccine. The reaction was more marked after the second or third inoculation than after the first as a rule. In comparing the leucocytic reaction with the clinical history in these cases the following conclusions have been made: 1. The stronger normal individuals show more reaction to subcutaneous injections of vaccine than the weaker ones who have had the disease and recurrent attacks. 2. The leucocytic reaction for the individual is more marked during or immediately after an attack of the disease and diminishes with recurrent attacks. This corresponds to the clinical observation that the resistance of the individual to the disease is lessened by a previous attack. 3. The fact that there may be a polymorphonuclear reaction to a subcutaneous injection of vaccine, coincident with the cessation of diarrhea, would indicate the use of vaccine therapy. In the few cases in which the treatment has been given, the results have been favorable for a recovery from the attack. A series of agglutination reactions was also done, using the sera of recovered and vaccinated patients and of immunized rabbits with the epidemic strains and also with several representatives of the paratyphoid enteritis group, one or more tests being made on 78 persons.

9. A Case of Blindness and Focal Infection Due to Ethmoiditis; Cured. Harry Rodman.

2. Erysipelas as a Complication of Mastoiditis.—Harold Hays expresses the conviction that erysipelas cannot be considered either a contagious or a directly infectious disease. He concludes that the disease does not occur as frequently as is thought from the fact that there were only 17 cases in the New York Eye and Ear Infirmary from January, 1912, to January, 1916. During that time between three and four thousand patients were operated upon for mastoiditis, which brings the ratio down to less than four per thousand. It was found that these cases occurred sporadically and that there was no direct infection from one patient to another. Apparently the character of the organism found in the ear or mastoid cavity had no definite relation to the development of this complication. In his experience he is inclined to believe the disease occurs more frequently in females than in males because of the maceration of the hair at the time of operation. On account of his belief that infection arises from this source he advises having the hair thoroughly washed before any operation on the mastoid. In the majority of cases of erysipelas complicating mastoiditis the onset occurred on the second or third day after the operation, though in a number of instances it occurred later. From his experience in private cases Dr. Hays considers the prognosis extremely good provided the patient has proper care and attention to his mastoid wound and provided the erysipelas is properly treated. The writer has found it impossible to combat the disease locally and believes that by far the most important part of the treatment consists in increasing the patient's resistance. It is preferable not to give such drugs as antipyrin, acetanilid, etc., on account of their depressant action on the heart. Aspirin, to which is added a small dose of caffeine, is permissible. No specific vaccines or serums seem to be effective, but Hiss leucocytic extract is almost a specific for uncomplicated erysipelas, particularly when it is associated with ear diseases. The writer has used the commercial extract in his private cases with brilliant results. The theory on which the leucocyte extract is used is that it increases leucocytosis and by so doing greatly improves the patient's powers of resistance. Dr. Hays reports one instance in which citrated blood taken from a convalescent erysipelas patient apparently effected a cure in a severe case of erysipelas complicated with bronchopneumonia.

6. A Paraffin Wax Treatment for Burns.—Charles Augustus Behney relates his experience in the treatment of burns with a preparation of paraffin, wax, and resin which he believes is as good as ambrine and comparatively inexpensive. He applies the wax with a soft camel's hair brush or atomizer and then places a layer of the thinnest absorbent cotton obtainable over the wax. A second layer of the wax is applied so that it completely saturates the cotton and firmly seals down the margins of the dressing to the sound skin. For additional protection a heavy layer of raw cotton is placed over all. The best results are obtained by redressing every twenty-four hours. Applied in this way the dressing is comfortable and can be removed without pain. For a period of time there may be active suppuration beneath the dressing, but this need not cause alarm, since it soon subsides and does not cause sepsis. This dressing enables the patient to become ambulant earlier; lessens toxic absorption from burns involving large areas; promotes the separation of devitalized tissues, and minimizes the formation of scars and contractures. It should be applied as soon as possible for the first dressing and should be used for all subsequent dressings. The formula is:

Paraffin (M. P. 40 C).....80 per cent.
Beeswax (yellow).....10 per cent.
White resin (turpentine)..... 3 per cent.

7. Etiology and Treatment of Bronchial Asthma.—Mark J. Gottlieb states that 27 of the 37 cases of bronchial asthma which they have had under their care had distinct nasal factors which were corrected, and in addition autogenous vaccines were administered. Seven had two series of injections consisting of fifteen doses. Five have been free from symptoms for over four years, and nine had a return of their symptoms, but they have stated that their attacks were not as severe or so frequent as before treatment. Ten patients were not benefited. The author concludes that bronchial asthma has always an underlying anaphylaxis, though the cause of the anaphylaxis is not the same in every case. The anaphylaxis may be multiple. In the majority of cases there is a superadded infection. The nasal accessory sinuses are the most important avenue through which infection occurs. Bronchial asthma is curable if the etiological factors are found and dealt with accordingly.

6. Observations on the Excretion of Dyes.—Russell L. Cecil and Richard Weil, in their studies on the excretion of dyes, observed that the dyes were excreted by external ulcers. This suggested the possibility that ulcers of the gastrointestinal tract might perhaps act in a similar fashion. They therefore studied gastric ulcers from this standpoint. Congo red was found in the stomach contents of a number of patients with gastric ulcer. In these cases it was usually present in very large amounts. In a number of cases of gastric carcinoma the same observation was made. On the other hand, there were some cases both of ulcer and of cancer which failed to give a reaction, while there were also occasional control cases in which neither ulcer nor cancer was present in which the stomach contents showed a small amount of the dye. In trying to account for the latter group they found that Congo red is excreted in large amounts in the bile, and that the reflux of bile into the stomach might present a severe complication in the utilization of the method as a gastric test. This fact led to a study of the excretion of dyes in relation to their excretion by the liver. Congo red is the only dye of which the excretion in the human bile has been directly investigated. It was found that injected into the blood the Congo red made its appearance in the bile in one-half hour, and continued to be excreted by that route for more than twelve hours. If dyes are to be used for the diagnosis of gastric conditions, it is essential to use such dyes as are not excreted by the bile. The method which the writers employed to determine whether dyes were excreted by the liver was to give an animal an intravenous injection, and then after two or three hours to aspirate the contents of the gallbladder. It was found that dyes could be divided into three classes in regard to their excretion by the liver. In the first group are the dyes which are excreted by the liver and are present in the bile. Among such dyes

may be mentioned, in addition to Congo red, neutral red, safranin, methylene blue, Biebrick scarlet, benzoazurin, and oxamin violet. The second group comprise the dyes which do not appear in the bile. Such are rosanalin, pyronin, trypan red, Orange G, eosin, indigocarmin, azur, and a number of others. The third group comprises those dyes which make their appearance in the bile occasionally, but not regularly, when injected in the routine amount of 0.5 c.c. of a 1 per cent. solution. Examples of this group are Bordeaux COV, Congo rubin, and azoblue. Further observations were also made on the effect upon the excretion of these dyes produced by first giving animals injections of phosphorized oil, which causes a marked fatty degeneration of the liver and an alteration in the degree of excretion. The results of these observations indicate the likelihood of finding some dye, the presence of which in the bile will always indicate a diseased process in the liver; as yet, however, this object has not been accomplished.

8. Edebohl's Operation in Nephritis in Children.—Dr. John Lovett Morse. (See MEDICAL RECORD, June 16, 1917, p. 1065.)

9. The Occurrence of Tubercle Bacilli in Breast Milk of Tuberculous Women.—Stanley L. Wang and Frederick Coonley have, during the past year, examined the breast milk of 28 tuberculous women at the Sea View Hospital, Staten Island, N. Y. The women had various types of tuberculosis and in various stages. The results of all the examinations were negative with one exception and that is considered questionable. Their observations indicate that tubercle bacilli are infrequently found in the breast milk of tuberculous women who have no mammary disease. The possibility of infection from such milk is probably slight, but it is very likely best to interdict nursing in every instance, because of the danger of infection through other avenues, the possibility of toxic substance in the milk, and the frequent bad effects of nursing on the mother.

1. Fatigue and Alcohol.—A. F. Stanley Kent in a recent address discusses the nature and causes of industrial fatigue, by which he means a diminished capacity for doing work, partly as a feeling of unfitness and being below par, and the relation of industrial fatigue to the taking of alcohol. A recent investigation of industrial fatigue shows that the reaction time of the abstainers is uniformly shorter than for those who take alcohol. The variations are also on a smaller scale, indicating that the effect of a day's work is less. Indeed, the average effect of a day's work in the alcoholics is five times as great as in the abstainers. He concludes that alcohol has little immediate effect upon the physical side of fatigue, whatever its ultimate effect may be. The amount of output is perhaps increased to a small extent for a short time, but the increase soon falls off and is replaced by a diminution. The influence of alcohol in the psychical side of fatigue is more profound. It leads immediately to a feeling of renewed vigor and increased strength. But here also the effect is transitory. Looked at from the other side, fatigue involves physical discomfort. The worker knows that this discomfort can be diminished by drink. Because the effect is transitory the dose will be repeated again and again, and industrial alcoholism will be established. Industrial alcoholism is a scientific problem and must be solved by attacking the cause, that is by improving the conditions that determine fatigue, by the provision of decent surroundings in the factory and in the home, adequate wages, leisure, and recreation.

2. On the Fallacies of Relying Solely on Agglutination Tests for Diagnosis of Typhoid Fever in Antityphoid Inoculated Individuals. With Special Reference to the Use of Dreyer's Method.—R. F. Garrow discusses this subject because of its great importance in military medicine. He believes that Glynn and Lowe, and Donaldson and Clark, diagnosed an unduly high number of cases as true typhoid among the enteric cases occurring in the Eastern Mediterranean. He believes that this can be explained by the fact that their cases were examined at a stage of their illness (late convalescence) when agglutination results are liable to be fallacious and that they even attached diagnostic significance to fluctuations which were possibly due to technical errors. The writer states that the result of these observers are sufficient to refute even the most modest interpretation of the claim that agglutination tests alone can be made to furnish a uniformly accurate diagnosis in cases examined during active infection. It cannot be too strongly insisted upon that agglutination tests by any method cannot be relied upon solely to furnish a diagnosis of enteric infections against which the patients have been inoculated. The official adoption of Dreyer's technic as a standard agglutination test in the Army, together with the teaching of the Oxford School of Pathology as to the diagnostic significance of an agglutinin fluctuation in an inoculated soldier would be disastrous to the enteric statistics of the Army.

4. A Contribution to te Study of "War Nephritis."—F. C. Davies and R. P. Weldon base their observations on 664 cases of "war nephritis" returned to a certain General Hospital from October, 1916, to March, 1917. During this period there were 173 medical and surgical autopsies, in 53 of which definite evidence of renal disease was obtained. Of the above 53 deaths, 26 occurred in patients diagnosed and under treatment for "war nephritis," giving a mortality for this disease in the period under consideration of 4 per cent. During the early part of this period cases of war nephritis were not numerous and were quite overshadowed by trench fever, while by March this latter disease had almost disappeared from the wards and war nephritis had largely taken its place. Many of these cases did not correspond to the published description of "trench nephritis;" some presented the clinical picture of bronchopneumonia, lobar pneumonia, or capillary bronchitis, whilst others were admitted with uremic coma, uremic convulsions, or uremic dyspnea without obvious edema of the head, trunk, or limbs. The fatal cases occurred without exception among the group simulating pulmonary disease and those admitted with uremia. The experience of the last winter shows that the disease has a much higher mortality than was suggested by the earlier published accounts. The autopsy findings in the fatal cases of war nephritis showed the kidneys nearly always enlarged and distinctly flabby. The capsule stripped fairly easy as a rule. The cut surface presented a cloudy appearance with eversion of the edges. The following features have been strikingly constant throughout the whole series: Degeneration of the epithelium of the convoluted tubules; absence of interstitial inflammatory changes; absence of glomular changes, except in seven cases that showed evidence of fibrosis, and absence of changes in the collecting tubules. In most of the cases the glomeruli were visible to the naked eye as minute granules. In contrast with the marked epithelial degeneration, the signs of interstitial inflammation have been singularly insignificant. A definite amount of fatty change of the tubular epithelium was present in every case examined. The evidence goes to show that one portion anl only one of the entire renal unit from glomerulus to pelvis bears the brunt of the disease, and this seems to eliminate the probability of a generalized bacterial infection of the kidneys, and equally to suggest that these same convoluted tubules are damaged in excreting a soluble poison, which may or may not be bacterial. Partial suppression of the urine is not infrequent in the early stages; later, however, a notable feature is the large quantity of urine secreted, even to three and one-half liters a day.

3. The Treatment of Scabies by Chlorine Gas. G. Herbert Clark and H. S. Raper.
4. Anaphylactic Shock After the Injection of Serum Intravenously. C. Adam Patrick.
5. Grave Diabetes Mellitus with Pulmonary Tuberculosis Following Mumps. F. B. Gilhespy and H. S. Holden.

3. The Treatment of Scabies by Chlorine Gas.—G. Herbert Clark and H. S. Raper have made an investigation as to the effect of "gassing" on scabies, about 60 cases of scabies in non-commissioned officers and men and 14 cases in officers have been treated by exposure to chlorine. The service gas helmet was worn by the men as a protection. The exposures were of five minutes duration and occurred on successive days. Usually four exposures were given but in some instances this number was exceeded. The patients were given a hot bath and wore ordinary hospital clothing. The concentration was between two and three parts of chlorine per thousand air. The number of exposures and the intervals between them were varied in order to find out the best conditions of treatment. Of the series of 60 non-commissioned officers and men not more than 25 per cent. were cured by this treatment. Of the 14 officers treated 11 were cured and three much improved. From experience with this group it seems that usually four exposures are sufficient, if given on the first, second, fifth and sixth days. The authors relate that numerous cases of scabies were occurring in a mounted section which was sleeping in temporary barracks. They were all passed through a considerable concentration of gas in a state of nudity, gas helmets being fastened about their necks with towels. The "gassing" was carried out in the sleeping quarters of the men, and all their clothing and bedding were widely opened and were treated by exposure to the chlorine fumes at the same time. The medical officers report that no case of scabies has occurred in this unit for two months that have elapsed since the gassing.

5. Grave Diabetes Mellitus with Pulmonary Tuberculosis Following Mumps.—F. B. Gilhespy and H. S. Holden report the case of a boy in the Royal Navy, 16½ years of age, who had an attack of mumps without any testicular or abdominal symptoms. On the third or fourth day of the disease his attention was called to the large amount of fluid he was drinking and he noticed that he was passing urine three or four times during the night which he had not been doing before. He developed marked symptoms of diabetes mellitus and later tuberculosis, dying five months after the attack of mumps. The point of interest in the necropsy findings aside from the extensive tuberculous condition was that sections of the head and body of the pancreas showed but little abnormality, while those of the tail showed, in addition to infiltration, hyaline degeneration of the islands of Langerhans. The affected islands were, however, rather scanty. The writers in commenting on this case say that abdominal symptoms have been but rarely described in mumps. In an epidemic of thirty-three cases, Edgecombe found that five of the subjects were affected with symptoms that pointed very definitely to an implication of the pancreas. Other writers have noticed the same train of symptoms occurring in the course of epidemics, and Morley Fletcher, in summing up their evidence, states that severe abdominal pain starts within a week of the onset of mumps, usually the fourth or fifth day, and is accompanied by vomiting and diarrhea. The same writer states that some cases of diabetes may date their origin from inflammatory changes brought about in the pancreas by an attack. Owing to the severe nervous strain imposed by the war it might naturally have been expected that diabetes, which has been experimentally shown to be associated with the chromaffin system would have become more frequent. From a careful analysis of the numbers of cases of diabetes treated at the Royal Naval Hospital, Plymouth, from January, 1911, to June, 1916, this expectation is justified. Out of 9,127 cases admitted to the hospital in 1911, 1912, 1913, there were five cases of diabetes, or 0.05 per cent.; whereas out of 7,968 cases admitted during 1914, 1915, and up to June, 1916, there were 22 cases of diabetes, or 0.27 per cent. Assuming that the navy has increased twofold during the latter period, the incidence of diabetes estimated on this basis has increased five-fold in the Plymouth Hospital.

Bronchospirochetoses and Bronchomycoses.—Castellani writes on the simulation by these affections of pulmonary tuberculosis. On the Adriatic-Balkan front this was present in 3 per cent. of all tuberculous soldiers examined. The spirochetic form, known also as Castellani's bronchitis, was first discovered in Ceylon in 1905-1906; and during the subsequent decade the affection has been recognized in many parts of the globe. There appears to be but a single causal spirochete which shows much polymorphism. The clinical features have been freely described in recent literature. Another condition, a group infection, the bronchomycoses, is also well known. Unlike bronchospirochetoses, the number of exciting causes is very large, and these are usually divided into groups as follows: I. Monilia, oidium, saccharomyces, etc. II. Hemispora. III. Aspergillus, penicillium, mucor, etc. IV. Nocardia, streptothrix. V. Sporotrichum. Most of these pathogenic moulds have been known for many years. But three species are of such clinical significance as to be associated with disease-pictures. These are represented in bronchomoniliasis, bronchooidiosis and bronchohemisporosis. The two first named conditions may be described together. The old nomenclature and description of these moulds has been revised by the author after artificial cultivation on certain sugars, which acts as a check on a purely botanical classification. He has differentiated 21 forms of monilia and 4 of oidium. The clinical picture set up by all these varieties is identical. There are two forms, mild and malignant and it is the latter which can simulate tuberculosis closely. The patient becomes thin and weak and has evening temperatures. The sputum, mucopurulent, may contain blood. The physical signs of bronchoalveolitis may sometimes be recognized—dullness on percussion, crepitant rales. The evolution is a matter of months and years and the termination fatal. In Ceylon the coolies who work in the tea industry present the affection, as known under the popular name of tea factory cough. The diagnosis is readily made from sputum examination and culture. Iodides are of benefit but cannot cure the severe cases. Bronchohemisporosis, the third or rather second clinical type cannot be said to present anything characteristic although the hemispora can cause severe lesions in the skin. It also can set up a malignant pseudotuberculosis and is likewise amenable to iodine treatment.

July 19, 1917.

Transfusion of Citrated Blood.—Hédon traces this resource to the early labors of Arthus and of Sir A. E. Wright with oxalated blood. These go back to 1891. The principle may never have been tested in mankind for sodium citrate was eventually substituted for the oxalate. The antagonism between calcium and sodium citrate in respect to coagulation of the blood was demonstrated by Sabattani in 1900. Further than these citations the author does not enter into the evolution of his subject. His own labors are purely experimental and represent a continuation of the research of the authors quoted. There is no reference whatever to the clinic or to mankind. He concludes that blood rendered incoagulable by trisodium citrate is perfectly safe to use in animal transfusion after a copious hemorrhage and states that the animals can be completely restored. The technique is very simple. A vein of the donor is punctured and aspirated by means of a syringe and needle, the barrel of the former having been previously charged with citrate in solution. The solution is then thrown into a vein in the recipient animal. The blood and solution are first mixed by shaking the syringe or the mixture may be thrown into a graduated glass with the same object.

Causes of Error in Wassermann Tests and How to Avoid Them.—Telmon refers to the various attempts made in recent years to simplify the Wassermann technique. In part these have to do with the use of the natural complement of the blood in which the serum is not heated, while in the other method the complement is inactive or previously warmed guinea pig serum. Leredde and others are partisans of non-heated

serum. Heating, they say in destroying the natural complement may also unfavorably affect the syphilitic amboceptor so that it may be present in small quantity only or be very unstable The two kinds of serum practically represent different reagents and cause much discrepancy in miscellaneous findings. Unwarmed serum is said to be superior to warmed serum in an entire series of cases. But aside from this source of discrepancy those who work with one method claim that paradoxical behavior is common enough to induce scepticism as to the trustworthiness of the reaction in diagnosis. The role of the antigen is of course much less important than once was believed, i.e., various antigens give the same result. But in regard to the question of fresh serum one must ask "is there a possibility that serum could be too recent?" We perhaps have to deal with a notable excess of complement when a serum is used immediately. In a positive case the excess of complement could cause hemolysis and vitiate the test. In the author's experience the serum should be at least twenty-four hours old. It is not uncommon to get a negative reaction at first and a positive one later. Sera rich in specific amboceptors may of course neutralize the entire complement. but generally speaking, the injurious excess should be suppressed. The serum should be first tested for its richness in complement. This test is one of relative hemolysis. A serum which hemolyses in less than five minutes is too rich in complement and should be retested in from twelve to twenty-four hours. If seven minutes are required for hemolysis, the serum should be of proper "age". We can therefore understand why paradoxical finds can come about through the age of the serum. In regard to inactivation by heat the author asserts that the drawbacks of this method can be obviated by the prolonged application of low heat—say for twenty-four to thirty hours at 38° C. instead of thirty minutes exposure at 56° C.

El Siglo Médico.

July 14, 1917.

Renal Insufficiency and Hemoptysis.—Pasanis enumerates the conditions under which hemoptysis occurs—affections of the bronchi, lungs, heart, and vessels, infections, suppression of habitual hemorrhages, etc. If a patient consults us for hemoptysis we first examine him for pulmonary tuberculosis and other affections of the bronchi and lungs, and if no lesions are found, examine the heart, and look perhaps for evidences of a bloodstate like purpura. If we succeed in excluding all these possible sources of bleeding we should look into the state of the renal functions. A case is related of a man who was subject to considerable hemorrhages from the lungs, averaging 80 or 90 gm. at a time. These occurred without evidence of either predisposing or exciting causes. A routine examination of the urine was at first negative. The appearance of the patient suggested tuberculosis and it was anticipated that this would ultimately be the diagnosis. The continued absence of temperature rise with relatively slow pulse, however, militated against this view. The second diagnosis, hemophilia, was entirely against the evidence and was quickly renounced, as was the possibility of a mitral stenosis, although a *bruit de galoppe* was heard at times. One year before consultation, patient had had a febrile affection accompanied by dysuria which apparently persisted. Arteriosclerosis could be excluded, and the author began to assume that the patient had gone through a simple nephritis which had left the kidneys compromised. There was not the least trace of albumin in the urine in some of the tests, although at times the tests were positive. The diagnosis lay between a latent chronic nephritis and a mere functional insufficiency of the kidneys due to an acute nephritis which had complicated a fever—probably typhoid. As far as could be ascertained, and judging from the outcome of the case, the renal insufficiency, if present at all, was temporary and ended in resolution. A study of the great clinicians and pathologists since the time of Bright shows that nephritis may be the cause of hemoptysis, hematemesis, epistoxis, purpura, etc. In rare cases it seems able to determine an acute hemorrhagic diathesis. But these losses of blood need not be due to nephritis *per se*, for they could be explained by the associated hypertrophy of the heart, hypertension from other causes, angiosclerosis, etc. The patient was placed upon the regimen for chronic nephritis with calcium chloride internally as a hemostatic. Within several weeks all his symptoms had disappeared and he was beginning to gain weight. During the elapsed four years he had not suffered from the slightest indisposition, and his health is now splendid. From the nature of the cure the author assumes that the hemoptysis was of renal origin. Although he writes much about blood analyses and retention of chlorides and nitrogen it does not appear that any such researches were made in the present case. The sole evidence of renal insufficiency appears to have been the intermittent leakage of albumin.

Correspondenz-Blatt für Schweizer Aerzte.

July 7, 1917.

Are Thermos Bottles Suitable for Keeping Milk Warm?—Von Bergen states that the socalled thermos bottles have come into general use not only in outdoor life but in household economics, especially in keeping warm the baby's milk. There are communities in Switzerland where neither gas, alcohol, nor petroleum is used in the household, and in such these containers are almost indispensable. The author, however, discovered that milk thus preserved can curdle in from six to eight hours. He believed at first that this event was due to poor milk, but upon investigation found that the latter had been normal to standard when placed in the bottles. He next suspected that the latter had not been properly cleansed, but after thorough disinfection the milk still curdled. The change in the milk was found to be due to butyric acid fermentation. The whey was turbid and sweet to the taste. Cultures gave the butyric acid bacillus. This organism grows energetically in sterile milk which it can curdle completely in twenty-four hours. There are two forms, motile and nonmotile, and both cause free production of CO_2 in the course of transforming lactose into butyric acid. Ordinary boiling is not sufficient to destroy the spores. The full explanation of the phenomenon is probably as follows: the milk is supposed to be boiled before going into the bottle, but to destroy the spores of the butyric acid it is necessary to boil for some time. Again at Leysin, where the author lives, the altitude above sea level is 1,400 meters and milk boils at 93° C., so that even prolonged boiling might fail to destroy the spores. The bacillus is also an anaerobe, and in the dearth of oxygen finds a stimulus to growth. Growth occurs only between 16° and 40° C., and as the temperature in the bottle is as a rule about 60° C., we can understand why the butyric acid fermentation occurs only exceptionally. The remedy is to bottle hot after first having heated the bottle to prevent breakage.

Excess of Women Among Suicides.—Spinner of Zürich quotes Swiss statistics in connection with this contention. It is known that women have been more prone to use poisons than are men, with the exception of doctors and druggists, which fact may in part explain the greater frequency of female suicides in some countries. On the other hand, there is an increasing tendency today among men of all classes to use poisons for suicidal purposes so that other factors must be sought which can affect the sex ratio. But as far as Switzerland goes, men still show a numerical superiority, although in 1912-1913 the sex ratio was practically fifty-fifty. In 1906-1907 the rule was reversed, for then more Swiss women than men killed themselves. However, the author's research has shown that for some unknown reason poisoning with illuminating gas has never been included in Swiss figures. If these cases are incorporated the proportion of female suicides shows an increase. During the past decennium there have been 474 suicides in Switzerland, the men leading with 56.1 per cent. An intensive study of suicide seems never to have been made. We do not know how many people are fatally poisoned, for example, and cannot determine the frequency of suicidal poisoning. The question of motive requires agitation. A woman who dies from an abortifacient, for example—under what circumstances is she a suicide? Suicides during pregnancy and menstruation, are they accidental, motivated, or done quite irresponsibly?

Book Reviews.

PULMONARY TUBERCULOSIS, Its Diagnosis, Prevention, and Treatment. By W. M. CROFTON, M.D., Lecturer in Special Pathology, University College, Dublin; Visiting Physician Royal National Hospital for Consumption in Ireland. Price, $1.50. Philadelphia: P. Blakiston's Son & Co.

THIS volume of scarcely 120 pages contains quite a good deal of information on the vast subject of tuberculosis. In the chapter on Bacteriology, the various microorganisms usually met with in the secretions of the tuberculous lung are enumerated. The *Micrococcus catarrhalis* and streptococci are justly mentioned as the most frequent factors in mixed infection.

The chapters on Anatomy, Histology, and Physiology, contain a number of excellent diagrams illustrating the topograhpy of the chest. In these diagrams the author designates as commonest sites of the first signs of tuberculosis, the region about the upper internal angle of the scapula, and the internal portion of the clavicle. As far as the posterior situation is concerned, the reviewer is in accord, but he is not willing to substantiate the author's opinion concerning the most frequent site of the first signs of tuberculosis anteriorly, for the first signs of an apical tuberculosis are quite as if not more frequently found anteriorly, near the external portion of the clavicle.

In the chapter on Diagnosis of Acute Miliary Tuberculosis in Doubtful Cases, such for example as those where the tubercle bacillus cannot be found in the blood-stained sputum, the author recommends lung puncture to obtain the exudate. This to the mind of the reviewer is a somewhat drastic procedure and not without danger. To hasten the resolution of the lung, the author gives the patient one or two doses of 1 to 2 c.c. of theosinamine sodium salicylate subcutaneously. By this means, Dr. Crofton claims to produce rapid dissolution of the fibrinocellular exudate in unresolved pneumonias, and tubercle bacilli, if present, will be more easily released.

As prophylaxis, the author states that for eight years he has urged all members of families whose parents were tuberculous to undergo a "short course of tuberculin T.R." He admits, however, the T.R. is not a very good antigen, neither can the ordinary tuberculin on the market be considered such, but that in his more recent experience the clinical results with tubercle bacilli dissolved in benzoyl chloride have been so satisfactory that he uses it also for prophylactic purposes.

In the chapter on General Therapeutics, nothing new is offered, but it is gratifying to see an endorsement of massage and passive movements for the non-febrile or very slightly febrile patient in bed prior to beginning walking exercises. With the author's recommendation that the laryngeal patient should be allowed to whisper, the review strongly disagrees. To whisper so that the average individual can understand, causes more or less strain on the vocal organs which should be at absolute rest when the larynx is involved.

In the concluding chapter the author describes his method of preparing his solutions of the tubercle bacillus with the aid of benzoyl chloride. He seems to be an enthusiast on the use of tuberculin and other sera for prophylaxis and treatment. He advises immunizing the patient against his catarrhal microbes before doing so against his tubercle bacilli. No statistics or corroborative statements of results obtained by the author's treatment are offered. The book is nevertheless worth careful perusal by those interested in modern phthisiotherapeutics.

PRACTICAL URANALYSES. By B. G. R. WILLIAMS, M.D., Director Wabash Valley Research Laboratory. Author of "Laboratory Methods," etc. Illustrated. Price, $1.25. St. Louis: C. V. Mosby Company, 1916.

A MANUAL covering every purpose for which its author has intended, that is, a guide for both student and practitioner in those diagnostic matters usually encountered from day to day in study or practice. One feature has been especially emphasized, the tests for the minor products of erroneous metabolism and excretion—proofs of disturbed function and its nature in certain tissues, organs, and systems, while therapeutic measures may yet offer relief or cure. It is in no way a usurper of more detailed, comprehensive works. On the contrary, the author strongly urges consultation of the larger laboratory books by the specialist or research worker for knowledge limited to any one branch of medicine. The book is so sensibly and well bound it deserves credit from this practical point of view also.

PERSONAL HEALTH. A Doctor Book for Discriminating People. By WILLIAM BRADY, M.D., Elmira, N. Y. Price, $1.50. Philadelphia and London: W. B. Saunders Company, 1916.

DURING the last decade or more, there has gradually arisen a popular interest in not only public, but personal health. This interest and curiosity has been fostered to a great extent by the newspapers all over the country as represented, in one instance, by the National Newspaper Service. The health talk department in the newspapers conducted through this channel has been in charge of physicians, one of whom is the author of this popular manual on personal health.

Never was a wiser movement started than this one catered to by the newspapers. What if, on the one hand, it does encourage the neurasthenics to become more deeply intrenched in their pet hobby of ill-health; on the other hand, it has opened vistas of encouragement to those who have a right desire to be thoroughly healthy and a wish to remain the same, through a realization that conditions which cannot be treated through the medium of the newspaper column require the services and attention of a nearby practicing physician.

The author has placed under one cover all the accumulated knowledge of most interest and benefit to the ordinary, intelligent layman, and he has presented it in such a direct, crisp, clean-cut style, there can be no mistake as to his meaning on the subject discussed. "The Catching Cold;" Adenoids and Tonsils; Heat and Ventilation; The Air We Breathe and the Air We Don't; Digestion, Metabolism, and Nutrition; Inside of the Chest, Cough; First Aid in Emergencies, and The Medicine Cupboard, cover some of his subjects. An excellent appendix giving directions for practical, household therapeutic measures is added.

MANUAL OF THE DISEASES OF THE EYE FOR STUDENTS AND GENERAL PRACTITIONERS. By CHARLES H. MAY, M.D., Director and Visiting Surgeon, Eye Service, Bellevue Hospital, New York; Attending Ophthalmic Surgeon to the Mt. Sinai Hospital, New York; Consulting Ophthalmologist to the French Hospital, to the Italian Hospital; Formerly Chief of Clinic and Instructor in Ophthalmology College of Physicians and Surgeons, Medical Department, Columbia University, New York. Ninth Edition, Revised. With 377 Original Illustrations, Including Twenty-two Plates, with Seventy-one Colored Figures. Price, $2.50. New York: William Wood & Company, 1917.

WITH the raising of the standard of admittance to medical colleges, there is coming too an improvement in the style of compilation of medical books. This naturally was bound to follow, and in many instances has been foreshadowed by the republication of certain medical works. These works must have had originally an appeal aside from the statement of true scientific facts, through a charm of style, good diction, and excellent illustrations which has carried them far ahead in favor among students and practitioners.

Among such is this work by Dr. May. It has reached its ninth edition August, 1917, following after an interval of only three years the eighth edition, which appeared in August, 1914, was reprinted in August, 1916, and again in February, 1917. Translations into eight different foreign languages have been made since 1904. While keeping abreast of the newest proved scientific data this latest edition has not been increased in size; the elimination of old material required to keep within its original size has been accomplished by sound judgment and common sense. The author states that the original plan of presenting a book for the student and general practitioner has been adhered to. To those whose power of thinking and ability to learn depend upon their mental visualization this book will prove an easy method of obtaining knowledge, for the illustrations are such that at times one might almost imagine that the patient sat in front of the examiner, so clearly and true to life have the many and various conditions been portrayed.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-ninth Annual Meeting, Held at White Sulphur Springs, W. Va., May 28, 29 and 30, 1917.

THE PRESIDENT, DR. FRANK SPOONER CHURCHILL OF CHICAGO, IN THE CHAIR.

Monday, May 28—First Day.

President's Address: The Responsibility of the American Pediatric Society in the Present National Crisis.—Dr. FRANK SPOONER CHURCHILL of Chicago delivered this address. He said, in part, that each and all of us were asking ourselves, "What is my duty—what ought I, what can I do to help my country in its present crisis?" These questions we asked not only of ourselves as individuals, but of societies and organizations. The advice to the individual had been "Do for your country that which you are best fitted to do." Similarly to the society or the organized group it could be said: "Let us do that which the nature of our organization makes possible for us to do well and efficiently." Clearly then the direction which the contributions and efforts of this Society should take was that which would best safeguard the child life of the country, not only from those dangers already existing, but from those that would inevitably arise as a result of the war. We might meet those problems in a twofold manner. First by continuing agencies already devoted to the interests of children, and, second, by making renewed and greater efforts to meet new problems. There was danger that the beneficent organizations devoted to the welfare of infants and children might be curtailed by cutting the appropriations to the public ones and by failure of subscriptions to the private ones. This would be suicidal and destructive. One of the most cruel results of war was its effect on the young and the helpless. The physical problems to be met had to do largely with nutrition and bodily sickness. There would be two groups of children requiring attention, the children of the poor and the children of enlisted men. The latter group must be the object of our special solicitude. It was within the power of this and other groups of pediatricians, by organized effort, to render great service to the children of these fighting men, not as a gift but as a just payment from us. This organization could well and profitably concern itself with an intensive study of food stuffs for the young, draw up diet lists embodying the results of such study, naming articles of food of proper nutritional quality, giving the caloric value, and, whenever possible, suggesting cheaper substitutes for the present high-priced articles. Equally important with the problem of nutrition of the child were the problems of a moral nature involved in the questions of child labor and delinquency. It was estimated that there had been in the warring countries an increase of 34 per cent. in juvenile crime and delinquency. Existing child labor laws should be enforced and juvenile protective associations should be heartily supported. Our part in this war was to fight in terms of the next generation. The quality of that generation would be the measure of our victory in the war.

Primary Carcinoma of the Liver in Childhood.—Dr. J. P. CROZER GRIFFITH of Philadelphia presented this paper in which he reported a case of carcinoma of the liver occurring in a female child, 21 months of age, whose family history was negative. The child had previously been in good health except for some degree of anemia, supposed to be dependent upon indigestion and a constant tendency to constipation. Midway between the midsternal and the right mammary line there was a decidedly visible prominence. On palpation this was found to be hard, smooth, and apparently connected with the liver. It changed its position distinctly with respiration. A provisional diagnosis of tumor or cyst of the liver was made. At operation, a dark gray, glistening, fibrous capsule, covering a tumor mass the size of an orange, was found in the right lobe of the liver. It projected slightly above the organ and extended in depth through the entire thickness of the lobe. The condition appeared to be inoperable and the wound was closed. Histological examination of a small portion of the tumor showed that it consisted entirely of epithelial cells without trace of liver tissue. The subsequent history of the case was that the growth continued to increase in size, sometimes rapidly and at others more slowly, until death occurred, about nine months after the case came under the writer's observation. The writer commented on the rarity of carcinomatous neoplasms in infancy and childhood and stated that carcinoma of the liver appeared to be more frequent than sarcoma. He reviewed 57 cases, 44 of which were collected by Steffen and Castle, and 13 additional cases which he had collected. Of this series 25 were males and 26 females. In others the sex was not mentioned. In this series of cases there were eight occurring in the first three months of life and 16 during the first year of life. The occurrence of so many cases suggests the existence of a tumor of embryonal nature. Of these cases some were simple carcinoma, some clearly adenocarcinoma, and others included provisionally were described as adenoma. The symptoms were entirely uncharacteristic and depended to some extent on the mechanical effect of the growths. The emaciation and cachexia natural to carcinomatous neoplasms was present. Icterus and ascites had been noted in some instances, but more frequently they were absent, or no statement was made regarding them. Operative interference was attempted in only one instance and that without success. It could only be done in the case of a single encapsulated tumor.

Intravenous Injections in Infancy.—Dr. CHARLES HUNTER DUNN of Boston read this paper, in which he said that the principal difficulty attending intravenous injections and transfusion in young infants had been the technical one due to the small size of the veins. The longitudinal sinus was a large vein very easily accessible through the open fontanel. This route was available not only for giving transfusions in hemorrhagic disease of the new born, but also for the giving of intravenous injections and medication. At the Infants' Hospital they had adopted the use of the longitudinal sinus for the purpose of obtaining blood for the Wassermann reaction and giving intravenous injections. The technic was extremely simple and apparently free from danger except when salvarsan was used. They had used the longitudinal sinus for giving normal salt solution, sodium bicarbonate in acidosis, antitoxin in diphtheria, circulatory stimulant drugs, and solutions of dextrose. It was the latter which the author said he wished particularly to consider. He had used intravenous injections of dextrose in cases of extreme atrophy and inanition produced by various forms of gastrointestinal disease. All the cases were either admitted to the hospital in an actually moribund condition or after admission became steadily worse under all ordinary methods of treatment. The theory upon which the intravenous injection of dextrose was based was that apparently the vicious circle produced by gastrointestinal disorder had become extreme and the digestion and absorption of sufficient fluid to furnish the energy requirement of the body was impossible. Dextrose was the only food substance that existed outside of the body in the same form in which it circulated in the blood and was utilized by the tissues. Consequently it seemed that introduced directly into the blood it might through the temporary supply of even a small quantity of fuel break the vicious circle for a sufficient length of time to permit improvement of the condition to take place. The author described the technique, the carrying out of which required three persons, but was otherwise simple. In determining the quantity of dextrose they had rather arbitrarily adopted a five per cent. solution. In choosing the quantity of dextrose for intravenous injection one-sixtieth of the body weight was taken. In 18 of these cases the records were sufficiently complete to report. In some of the cases the improvement which followed the injection was so immediate and striking that it seemed that there was a possibility at least that the injections had produced the good result. Of these 18 cases, 13 died and five recovered. In all a fatal ending had seemed imminent. Six showed a very striking improvement immediately after the injection. There was, however, no evidence that improvement, even if it was due to the intravenous injection, was

due to the dextrose. The giving of fluid into the circulation in cases of this character was of itself a therapeutic measure of known value and it was quite possible that the improvement was due to the fluid and not to the dextrose. In the writer's opinion there was sufficient possibility of the dextrose being of value to warrant its further trial. Careful urinary examination in these cases showed that whether or not the dextrose produced a favorable result it was at least utilized in the child's metabolism. In five cases more than one injection was given. In one case six injections of three grams each of dextrose were given, and in this instance the patient seemed to be practically kept alive by the dextrose and eventually recovered.

Dr. HENRY F. HELMHOLZ of Evanston, Ill., said that they had been doing similar work. Dr. Woodyatt had devised a pump by which they were enabled to introduce the sugar solution at a uniform rate and the rate could be varied at will. They had found that with the injection of about 0.8 of a gram of dextrose per kilo body weight no sugar would be excreted in the urine. He thought that in the concentration in which they had used the dextrose there was no danger of overloading the circulation and putting too great a strain on the heart.

Dr. GODFREY R. PISEK of New York described a syringe which he had been using, by which it was possible to withdraw the fluid in the usual way and then to make the injection by the gravity method. This provided an additional element of safety and eliminated the possibility of running the fluid in too rapidly.

Dr. HOWARD C. CARPENTER of Philadelphia warned against the injection of too powerful drugs by this method. He related an instance in which salvarsan was given by a technique supposed to be properly carried out. The child died about eleven days afterward and autopsy showed an abscess on the frontal lobe of the brain.

Dr. ALFRED F. HESS of New York related a case which he said had impressed him to such an extent that he hesitated to enter the longitudinal sinus in hemorrhagic cases.

Dr. JULIUS P. SEDGWICK of Minneapolis said they had been using this method of going through the longitudinal sinus. In a few instances in hemorrhage disease he felt that it had been a life-saving procedure.

Dr. HENRY F. HELMHOLZ of Evanston, Ill., said he had seen three cases within the last three months which had resulted fatally after injections into the longitudinal sinus. They were not his own cases. In all three cases the injections were very carefully given and at autopsy the entire cortex as well as the base of the brain was covered with blood. It was possible that some pathological condition and not the injection was to blame.

Dr. CHARLES HUNTER DUNN of Boston said it would probably be safe to give stronger solutions of dextrose than they had given, but in the beginning of a work of this kind it was necessary to proceed very cautiously. In giving medication by this route it might be well to make an exception of salvarsan.

The Therapeutic Use of Horse Serum.—Dr. ROWLAND G. FREEMAN of New York presented this paper in which he stated that he had been so impressed with the results of an injection of blood serum in a case of hemorrhage in a new born infant that although there might have been nothing unusual in this case, it had brought the question to his mind whether this treatment might not be applied to other conditions with good results. Of the various conditions which we always had with us and in which our results were not good with ordinary methods of treatment was marasmus. He had at this time in his service at Roosevelt Hospital a baby, 7 months old, that came in weighing 12½ pounds. Though fed on different promising foods except breast milk, this infant continued to lose. One month after his admission it was found that he had lost a pound and he appeared to be practically dead. He was given hyperdermoclysis, 250 c.c. This was followed by a rise in temperature and an increase of several ounces in weight. On the following day 20 c.c. of horse serum were injected. This was followed by a temperature reaction up to 102° F., as occurred on two following days when he received injections. Seventeen days after the institution of this treatment the child had gained one and three-quarter pounds and the treatment was given only every second day, a larger amount of horse serum being given. A little less than a month after the treatment was commenced the child's condition was so satisfactory that the injections were discontinued and the child went on to a complete recovery. This baby, in the writer's opinion, would most certainly have died without this treatment. Recently Dr. Freeman had had on his service at Roosevelt Hospital four babies at the same time with a weight of five or six pounds, all being about two months old, and all having been labored over with all sorts of foods. Treatment in these cases was started on the same day. The histories of these cases seemed to show that when the injections were stopped the improvement was not so rapid, and indeed there would be a loss in weight, but as soon as the injections of horse serum were resumed there would again be a gain in weight. After two injections of horse serum it was advisable to again test the child for sensitization before a third injection was given. One case of miliary tuberculosis with consolidation and cavitation, which had lost from twenty-six to eighteen and one-half pounds and under heliotherapy, and then gradually gained to twenty-six pounds at which point she remained stationary for weeks, was given 20 c.c. of horse serum, which was repeated once when she began gaining. Dr. Freeman stated that he did not hold that this treatment was in any way a panacea, but that under proper control it was a safe procedure and in some almost hopeless cases it apparently produced marked improvement. He believed it had a much greater sphere of usefulness than had hitherto been appreciated. It seemed of no use to give injections of less than 20 c.c. of serum.

Dr. CHARLES HERRMAN of New York said that they had had an epidemic of the type of cases described by Dr. Freeman. They had had some twenty-six cases, two of which were very severe, and it seemed probable that they would die. They were given injections of horse serum with very good results. Theoretically human serum would be better than horse serum. As a rule it was not difficult to get human serum for babies as the parents were usually willing to act as donors. The question was whether it was necessary to use serum, whether the whole blood would not be just as good as the serum.

Dr. FRITZ B. TALBOT of Boston said it would be interesting to know what Dr. Freeman had done for the future of these babies, particularly the one that developed a reaction after one or two injections of the horse serum, to what degree they would be sensitized. Dr. Talbot said he was not so much impressed by these charts as he would like to have been. He had seen a similar improvement take place in cases of this kind without this form of treatment.

Dr. L. EMMETT HOLT of New York asked what proportion of the cases treated in this way the charts represented, and whether these were the only satisfactory ones. He said he agreed with Dr. Talbot that one sometimes saw similar results in cases not treated in this way. There was one case, however, in which the results were very striking.

Dr. ROWLAND G. FREEMAN of New York, in closing, said that horse serum was more easily available than human serum and one could get it in any quantity. In the one case that was given so many injections treatment would have had to be discontinued had they been dependent upon human serum. He did not think it made much difference whether they used human serum, or horse serum, or whole blood. As to the possibility of having sensitized these babies to horse serum these were practically dying babies and the question of sensitization was at the time a minor one. The results of the treatment in two of the cases were very striking. Dr. Freeman said he was not sure that this treatment was worth a great deal but it seemed to be worth enough to warrant bringing it before the society to see what the members thought of it.

Twenty-four Hour Metabolism of Two Normal Infants with Special Reference to the Total Energy Requirements of the Infants.—Dr. FRITZ B. TALBOT of Boston presented this communication, which consisted in a continuation of the series of investigations of the metabolism of normal infants begun five years ago by Benedict and himself at the Nutrition Laboratory of the Carnegie Institution of Washington. The present in-

vestigation was made to determine, if possible, how much energy was expended in the ordinary muscular activity of an infant during a twenty-four hour day. If the increase in metabolism due to muscular activity could be determined, if the factor of growth and the factor of energy lost in the excretions could be established, this material could be used in conjunction with the curve of basal metabolism to estimate the number of calories necessary in a twenty-four hour day. One of these infants was in the respiratory chamber twenty-two hours and thirty-one minutes, and the other twenty-three hours and ten minutes. The length of observation compared favorably with those of Rubner and Hubner, which were in all instances shorter. Accurate records were kept of the time during which the infants were nursed, the time during which they cooed, kicked, played, smiled, cried, and were changed. It was found in the first baby that the basal metabolism of 285 calories was increased 143 calories by muscular activity. This corresponded with an increase of 67 per cent. The basal metabolism of the second baby was increased to an extent corresponding to 70 per cent. by muscular activity. Since the babies were removed from the chamber at regular intervals during the twenty-four hours for their usual nursings, their metabolism could not be measured for that time, but an estimate of what it would have been was considered justifiable. This allowance calculated very carefully was estimated as seventeen calories, and this was added to the measured metabolism and gave the total calories produced in twenty-four hours. There were, however, other ways in which energy might be lost from the body, such as the potential energy of the urine and feces. This energy which was lost must be supplied in the food. Presumably the greatest single factor was the fat lost in the feces, which with the urea in the urine would not exceed 15 per cent. of the total measured metabolism in a normal infant. A rough estimate of the caloric requirement of the normal infant might then be made by adding the calories used up in muscular activity to the basal metabolism. If the infant was very quiet 15 per cent. should be added, if normally active 25 per cent., and if extremely active 40 more or less per cent. To this result 15 per cent. should be added for energy lost in the excreta and 20 per cent. for growth. In the case of the first baby, E. L., they knew how many calories were actually used up in muscular exercise, therefore all that was necessary was to add the probable amount of calories necessary to allow for growth and what was lost in the excreta. That was 35 per cent., which was added to the 74 calories per kilo of body weight actually used by this baby, and it was thus found that she needed about 100 calories per kilo body weight in her food. If the same process was followed out with the second baby the food requirement was found to be 94 calories per kilo body weight. The writer made the practical suggestion from these observations that it was probable that infants fed on cow's milk, and particularly on formulas containing large amounts of protein, would require even more food than infants fed on breast milk, because the stimulating action of the protein caused extra heat to be burned during digestion. The caloric requirements of sick babies were obviously not the same as for normal infants, since the basal metabolism of the sick infant was higher per kilo body weight, neither did it apply to the infant with a subnormal temperature which indicated depressed vital functions.

Dr. Thomas S. Southworth of New York asked Dr. Talbot if any calculations had been made as to how much energy was used up in the changes in temperature to which babies' bodies were exposed as when the lower extremities were exposed. He had recently been consulted regarding a child that was dressed without shoes or stockings and had told the parents that the baby would do better if its feet and legs were covered, and if it did not waste energy through a loss of heat that should go into growth. An English authority has estimated that a certain number of ounces additional nourishment must be given to provide for the loss of heat when certain portions of the body were exposed.

Dr. Charles Hunter Dunn of Boston asked what evidence there was that there was such a thing as a normal infant. The factor of individual variation came into an enormous extent if one took only two, three, or five babies. If there were enough observations made one could arrive at a standard of averages, but he had always felt that this was a great mistake foreigners had made. If one took a number of figures and divided their sum by a number of cases the result was never applicable to any individual infant.

Dr. Godfrey R. Pisek of New York said that they should be very grateful to Dr. Talbot for this piece of work. He thought, however, that the estimate of the amount of energy the child used when out of the respiratory chamber was low, particularly the amount of energy used in nursing.

Dr. B. Raymond Hoobler of Detroit said Dr. Talbot was to be congratulated on being able to make a metabolism observation covering twenty-three hours. This had not been done before. The best that Dr. Rubner had been able to do was to get observations covering nineteen hours and some minutes. Rubner had found 100 calories per kilo body weight the average requirement of an infant under six months of age. Dr. Talbot's estimate would exceed just a little 100 calories per kilo body weight, so that this estimate must be very near the truth. He thought we were finding that nearly all active children required more than 100 calories per kilo body weight. All of Dr. Talbot's calculations had been worked out very nicely.

Dr. Talbot, in closing, said that in regard to the loss of heat from exposure, the surrounding temperature made no difference unless there was chilling, and then when the baby shivered he produced heat. If he did not perform additional exercise he did not produce more heat. The figures presented might not be applicable to older children, but they were applicable to newborn babies. It was a mistake to give a newborn baby a water bath at the time of birth, since it might result in a subnormal temperature and then there would be a lowered metabolic activity and all the vital functions would be depressed. If the newborn baby was strong enough to shiver and cry it then produced heat and was able to withstand the shock. A point of importance with reference to muscular activity was brought out by Dr. Lusk in an investigation in a boys' school. These boys were very active and the number of calories they were getting were carefully estimated. It was found that they were eating one and one-half times as much as a laboring man.

Studies on Blood Calcium — The Calcium Partition Distribution in Ox Blood and in Man's Blood.—Dr. David Murray Cowie of Ann Arbor read this paper. He said that they had carried out this investigation because of the difference of opinion as to the distribution of calcium in the blood. The practical side of the question had to do with the question of whether it was more expedient and more accurate to use serum or whole blood for the estimation of blood calcium. Hitherto in the employment of whole blood for making these estimations considerable difficulty had been experienced in ashing. This they believed they had overcome by a method employed by them last year and still further perfected by Dr. Lyman. The scope of their work had been to determine the calcium content of the whole blood, of normal serum, of serum from defibrinated blood, the calcium content of the unwashed corpuscles obtained from citrated blood, of washed corpuscles obtained from defibrinated blood, of washed corpuscles obtained from citrated blood, the power of the blood corpuscles to combine with calcium, and the character of the combination of calcium with blood corpuscles. The present communication consisted of a preliminary report on the calcium partition and distribution in ox's blood and in man's blood. In making their calculations they had to consider the relative proportion of serum and formed elements in a given sample of blood. For instance, in ox's blood 32.55 per cent. of the whole blood was composed of formed elements, corpuscles 67.45 per cent. of serum. In man's blood 51.302 per cent. was composed of formed elements, 48.698 per cent. was serum. Calculated on this basis, they had found that the calcium content of whole blood was definitely greater than that of an apportional amount of serum. One must admit that the corpuscles were not negligible. Calculating the amounts of calcium in the serum and corpuscles, respectively, of 100 c.c. of ox's blood and of man's blood showed that the serum of ox's blood contained more calcium than the serum of man's blood; that the corpuscles and fibrin of man's blood contained more calcium than the corpuscles and fibrin of ox's

blood, and that the whole blood of man contained more calcium than whole ox's blood. The possibility of a variation in the relative proportion of corpuscles and serum under altered states of the organism must also be taken into consideration. There was more serum per volume of blood in severe anemia and hydremia. The Lyman method was well adapted for the study of either the corpuscles or the serum, and with proper equipment and reliable chemicals was of clinical utility.

The Uric Acid Content of the Blood in Newborns.—Drs. JULIUS P. SEDGWICK and KINGSBURY of Minneapolis presented this communication, which was read by Dr. Sedgwick. He stated that it had long been well known that the uric acid excretion in the urine during the first few days of life was both relatively and absolutely high, that during this period rapid morphological changes occurred in the blood, such as the disappearance of the nuclei of many of the red cells, the change in proportion from a predominating number of polymorphonuclear neutrophiles to a corresponding preponderance of lymphocytes, and the striking decrease in the leucocyte count of the peripheral blood. The polymorphonucleosis dropped rapidly from the second to the fifth day. Nucleoproteins set free by the leucocyte destruction had been considered the source of the well known high uric acid excretion of the first week. The present investigation was made in order to determine whether or not the high uric acid excretion during the first few days of life was accompanied by a simultaneous increase of this substance in the blood. The determination of the uric acid was made by the modification of the Folin-Denis method devised by Myers, Fine, and Lough. The weights of the blood samples used in these analyses varied from nine to eighteen grams and were drawn from the superior longitudinal sinus of newborns. The placental blood was collected as soon as possible after cutting the cord, which was done after the cord had stopped pulsating. The maternal blood was drawn from the arm of the mother at the time of parturition. All the newborn subjects were normal. It was found that the average values of 16 determinations of the uric acid content of maternal and placental blood were identical, being about three milligrams per 100 milligrams of blood. This agreed with the independent findings of Slemmons. In some instances the infants were given water in addition to their ordinary diet of breast milk. It might be observed that the content of uric acid in the blood during the first three or four days after birth was higher than that of the blood of the same newborn at the time of birth. In seven cases there was a marked decrease in this value at the end of eight to eleven days from the value obtained three to eight days earlier. It was noted that in the period between the second and third days that the value reached a maximum. During the first three or four days this value was higher than the maternal and placental figures. From a maximum of 3.9 milligrams the blood uric acid fell off slowly to 2.9 milligrams on the fifth day and then rapidly to 1.6 on the eighth to the eleventh day. This value agreed with the finding of Liefmann in the blood of the thriving children from nine weeks to fourteen months of age, on a pure milk diet. The findings also supported those of Wells, Corper, and others (in opposition to the results of Schnittenhelm and Schmidt) that human fetal tissues possessed no urilytic power. These results fitted well as the connecting link in the theoretical chain of early leucocytosis, fall in leucocytosis, flood of uric acid in the blood, high uric acid excretion, and uric acid infarcts.

Dr. FRITZ B. TALBOT of Boston said that this was one of the very obscure periods of infancy. Dr. Sedgwick had given them material which he hoped would open up the way to further investigations in the newborn about which so little was known.

Dr. PERCIVAL J. EATON of Pittsburgh said that he understood that some of these babies were getting water and others were not, and he would like to know whether Dr. Sedgwick had noticed a greater concentration of uric acid in the urine of those babies that were not getting water.

Dr. SEDGWICK replied that he had not made any examinations of the uric acid excreted in the urine, only the uric acid content of the blood.

The Salts in Green Vegetables and the Effect of Different Modes of Cooking.—Dr. FREDERICK H. BARTLETT of New York read this paper, in which he said that the practice of adding green vegetables to the dietary of young infants was becoming a common practice. It was believed that their value was due to their effect on the mineral metabolism. Instead of making use of drugs to supply the needed iron, green vegetables had been fed to many children in the wards and the outpatient department of the Babies' Hospital. The plan had been followed with children as young as six or seven months. Infants thus fed had shown an earlier closure of the fontanel and generally greater activity than those fed without such additions to their diet. The general opinion was that the mineral content was the important factor, and they had studied the subject from this viewpoint. They had studied the actual mineral content of the vegetables as ordinarily prepared and administered. They had analyzed cooked vegetables, considering separately the solid portion ordinarily given as food and the water used in cooking. They had estimated the content in grams of the solids of vegetables prepared by boiling, taking spinach, New Zealand spinach, young carrots, string beans, asparagus, and potatoes, estimating the solids, ash, calcium, magnesium, phosphorus, potassium, sodium, sulphuric acid, iron, and the total nitrogen and nitrogen as protein. They had estimated the percentage lost in the water with long and short boiling, and compared the percentages lost in water by steaming and by boiling, the content in grams of vegetables prepared by steaming of the various constituents, and the approximate content of one tablespoonful of steamed vegetable of the various constituents. Spinach showed the highest total salts. It contained from two to three times as much ash as any of the other vegetables studied. The preponderance was largely due to calcium and phosphorus. The iron was highest in New Zealand spinach, ordinary spinach and carrots coming next. The iron in onions was very low, while asparagus had only a trace. Spinach was the most efficacious in supplying mineral salts. New Zealand spinach possessed the advantage of being available for a continuous supply all summer. The analyses showed an excessive waste of salts if the water in which the vegetables were boiled was thrown away. Calcium was the only constituent not affected by boiling. Steaming was then tried and found to be the most economical method of cooking for preserving the salts. Any type of steamer which held the vegetables out of water would undoubtedly serve the purpose. In spinach the loss by steaming was about one-half what it was by boiling. One hundred grams of the edible portion of uncooked vegetable when cooked yielded approximately three tablespoonfuls; this was true of all vegetables but carrots, which yielded about four. The effect of steaming on New Zealand spinach was more variable than in the case of other vegetables.

Dr. GODFREY R. PISEK of New York said that many young children did not like vegetables. He would like to ask Dr. Bartlett how he got the infants to eat the vegetables, and whether he fed them through a bottle.

Dr. J. P. SEDGWICK of Minneapolis said that experiments in this line had been made in the Department of Household Economics of the University of Minnesota which showed the importance of retaining the salts of green vegetables and the amount retained with different methods of cooking. Experiments of F. B. Roder showed the retention of calcium in the feeding of a vegetable free diet and when vegetables were given to children. They had also endeavored to find the amount of calcium which it was necessary to administer in order to produce calcium retention. They found that an enormous amount was required and that the small amounts usually given therapeutically were a farce.

Dr. L. EMMETT HOLT of New York emphasized the importance of careful attention to the minute subdivision of all vegetables fed to infants. The difficulty caused by particles of undigested vegetables might be entirely obviated by rubbing the vegetables through a fine sieve. They were doing this in the hospital and it was surprising how little effect vegetables prepared in this way had upon the infant's stools. One mistake that could not be emphasized too often was that of allowing a child to have the bottle for two years. One met with some of the worst types of malnutrition in such children.

Dr. PERCIVAL J. EATON of Pittsburgh called attention

to the fact that the water in which vegetables were boiled could be used as soup stock or added to bean or pea soup and thus the mineral salts would be conserved.

Dr. Rowland G. Freeman of New York said it had been his experience that children with poor digestive capacity did not take vegetables well.

Dr. Percival J. Eaton said he thought if Dr. Freeman would see that the vegetables were rubbed through a sieve he would find that the children digested them well.

Dr. Isaac Abt of Chicago said they were using a mill with two closely adjusted plates for pulverizing vegetables and other foods and that this did the work very effectively.

Dr. Henry Heiman of New York said his experience had been somewhat similar to that of Dr. Freeman. He thought we must not lose sight of the fact that we had unsplit carbohydrates as well as unsplit proteins. Their experience in New York showed the necessity of giving babies vegetables as early as possible.

Dr. David M. Cowie of Ann Arbor said they had had some difficulty from attempting to use as much spinach as they did carrot; one could not use as much spinach as carrot.

Dr. Helmholz referred to an article recently published which showed that vegetables, dried and pulverized and then made into the finest emulsion possible might be fed to infants two or three months old without any ill effect.

Dr. Frederick H. Bartlett of New York, in closing, said that if the vegetables were rubbed through a fine sieve they could be fed either through a bottle or with a spoon. It was a mistake to begin feeding a baby as much as a tablespoonful of vegetable. One should begin with a very small quantity.

Congenital Skin Defects.—Dr. Isaac Abt of Chicago presented this communication, in which he commented upon the infrequency with which congenital skin defects had been reported in the literature, and the fact that the majority of reports dealt with defects of the scalp. He stated that most writers attributed their cause to either errors of development or to inflammatory adhesions between the external layers of the skin and the amnion. Not infrequently these skin defects were associated with other malformations such as deficient fingers, hands, or feet, caused by the action of the amniotic bands. These lesions were found most frequently on the scalp, though Emanuel reported a case with congenital skin lesions occurring on the hands, legs, feet, over the temples and bridge of the nose, and also an area in the middle of the lumbar region. These defects seemed to bear no relation to trauma at birth and undoubtedly originated *in utero*. Occurring singly or in groups, they presented ulcerated areas which affected both layers of the skin. The subcutaneous tissues were not involved. These ulcerated areas were sharply defined, somewhat irregular in outline. The base of the ulcer was red and secreted a thin lymph. In some of the recorded cases the defective skin areas developed hairs later in life. Microscopically the area showed the lack of epithelial structure, smooth muscle, and adipose tissue. The skin glands developed if at all in a rudimentary manner. The majority of these lesions tended to cicatrize in a short time. The case which formed the subject of this report was normal at the time of birth, except for two defective areas over both knees. The labor was normal. The areas in this case were about one and one-quarter inch in diameter, symmetrical, and seemed, so to speak, irregularly punched out. The skin around the edges was drawn and puckered, presenting the appearance of an ulcer. The base was beefy red and moist and small areas of the ulcerated surface showed a yellowish exudate. A whitish scar seemed to cross the ulcerated areas as though connective tissue bands indicated the beginning of a process of citratrization. The ulcers from week to week became more and more cicatrized and after five or six weeks were replaced by shiny white patches. A review of the cases reported in the literature was presented, giving the sex, age, localization of the lesion, and other data.

Dr. Julius P. Sedgwick of Minneapolis said that last winter they had had a case of congenital defect of the scalp. He felt sure that if newborn infants were turned over to the pediatrist more of these cases would be observed.

Enlargement of the Thymus Treated by the X-Ray.—Dr. Alfred Friedlander of Cincinnati presented this paper, in which he emphasized that enlarged thymus was more frequent than was ordinarily supposed; that the diagnosis could be made definitely by means of simple physical examination and the *x*-ray; that in the *x*-ray we possessed a therapeutic agent which in and of itself would effect a cure in the vast majority of cases. In their studies of this condition they had found that quite a number of cases had occurred in babies suffering from congenital syphilis, though at present no conclusions could be drawn fom this observation. A distinct familial tendency had been noted. They had also observed an apparent relationship between hypertrophic stenosis of the pylorus and enlarged thymus. Some cases of enlarged thymus ran a symptomless course. Sudden death as the result of trauma, anesthesia, or intercurrent affection occurred not infrequently in these cases. Intercurrent affections frequently lit up the pressure effect of an enlarged thymus. There were three definite symptoms of enlarged thymus, which were present singly or together, namely, dyspnea, continuous or intermittent; suffocation attacks with cyanosis, and stridor. The dyspnea might be either permanent or intermittent. Stridor when present was usually inspiratory. The diagnostic physical signs of greatest importance were the detection of a bulging mass in the jugular, oftener absent than present, and enlargement of the area of normal thymus dullness on percussion. In young children there was a definite form of thymus dullness in the shape of an irregular triangle or truncated cone whose base was the sternoclavicular junction and whose apex was the second rib. The percussion of the area of thymic dullness was not difficult if one used very light or at times threshold percussion. Dr. Sidney Lange of Cincinnati had worked out a very careful technique by which definite information as to the existence of thymus enlargement was afforded by the *x*-ray. The child must be absolutely flat on his back and the exposure must be absolutely instantaneous. In the series of *x*-ray pictures presented the exposure had varied from one-sixtieth to one-thirtieth of a second. A very soft *x*-ray tube should be used. The technique as worked out by Lange was remarkably simple. A Coolidge tube backing up a nine and one-half inch spark was employed. The rays were filtered through four millimeters of aluminum and a piece of thick leather. The target skin distance was approximately nine inches. The routine exposure was 25 milliampere minutes. In mild cases a single dose given over the anterior surface of the chest proved sufficient. In more urgent cases 50 milliampere minutes were administered at the first treatment, 25 anteriorly and 25 posteriorly. The interval between treatments was usually one week, unless urgent symptoms suggested the advisability of more frequent treatments. To guard against sudden death before the full destructive effect of the *x*-ray upon the thymus had been elicited, all cases with urgent symptoms should be kept under close observation and the *x*-ray treatments pushed boldly. In the average case improvement of symptoms had been noted within 24 to 48 hours after the *x*-ray treatment; in many a very decided improvement was noted in two weeks' time or even less.

Dr. Howard C. Carpenter of Philadelphia referred to the work of Dr. Pfahler of Philadelphia, who had been treating this type of cases with uniformly successful results. In a few instances almost instantaneous improvement had followed this treatment.

Dr. William Palmer Lucas of San Francisco said he had found practically the same type of picture in children without clinical symptoms, and had followed the children for months without any symptoms arising. In cases of enlarged thymus and symptoms he had obtained the same results with the *x*-ray treatment, with practically the same dosage as Dr. Friedlander, but not in two weeks.

Dr. Fritz B. Talbot of Boston said that they had been seeing practically the same results as Dr. Lucas had shown in the treatment of enlarged thymus by means of the *x*-ray. They had had one case four or five years ago in which the symptoms disappeared under *x*-ray treatment that returned last spring with a recurrence of the symptoms that required a long course of treatment.

Dr. David M. Cowie of Ann Arbor said he had had children sent to him with the report that the *x*-ray showed enlarged thymus in which he could not confirm that diagnosis. Again he had had typical cases of enlarged thymus which were not shown by the *x*-ray.

Dr. J. P. Crozer Griffith of Philadelphia said he believed there was such a thing as thymic asthma and that death occurred from it. He had seen this condition steadily disappear under *x*-ray treatment. Thymic enlargement was an accompaniment of status lymphaticus, and the symptoms and results that they saw were due to pressure and not to the thymus gland alone.

Dr. Alfred F. Hess of New York called attention to the possibility of mistaking the picture produced by an enlargement of the vessels at the base of the heart for enlarged thymus. This picture was sometimes seen in children with scurvy and in adults with beriberi. In taking *x*-ray pictures of babies he had found that some of the controls gave pictures just like those of thymic asthma, yet there were no symptoms of thymic asthma.

Dr. F. S. Churchill of Chicago asked how long the cases had been under observation.

Dr. Friedlander said that some cases of enlarged thymus might give no symptoms while others might produce pressure effects or the symptoms of hyperthymus. As some symptomless cases resulted in sudden death, and the thymus was an organ that enlarged and diminished very rapidly, the fact that there were no symptoms was no reason for stopping *x*-ray treatment. He had studied a large series of cases and found that in cases in which there was an enlarged thymus, if marked congestion occurred as from whooping cough or bronchitis, it might light up the symptoms and cause the death of the child. If we got a shadow that might lead us to suspect that it was due to enlargement of the vessels at the base of the heart, if two or three *x*-ray treatments were given and the picture again taken, the diagnosis would be cleared up. The first case was treated in 1903 and was now hale and hearty. Several of these cases went back to 1903 and others were very recent.

Focal Lesions Produced in the Rabbit by Colon Bacilli Isolated from Pyelitis Cases.—Dr. Henry F. Helmholz and Miss Carol Beeler of Evanston, Ill., presented this paper. Dr. Helmholz stated that in order to determine whether pyelitis could be produced by the hematogenous routes two series of experiments were performed on rabbits. In the first series sixty-six animals were injected intravenously with eight different strains of colon bacilli. Of these twenty-six showed focal lesions of one kind or another. The organs affected were as follows: Kidneys, eleven times; cecum, seven times; gallbladder, seven times; appendix, five times; stomach, four times. In addition there were single instances of hemorrhagic infraction of the descending colon, ulcerative colitis, hemorrhagic enteritis, and duodenal hemorrhages. Thus the organism did not show any special tendency to localize in the kidney and focal lesions were just as likely to appear in any organs of the gastrointestinal tract. In 90 per cent. of the instances the rabbit could excrete colon bacilli through the kidney without harm to the kidney itself. In the second series of experiments a mixture of colon bacilli and pneumococci were injected into eleven animals. The kidneys were infected in six of the animals, or about 60 per cent. It therefore seems possible that the relative number of kidney infections was greatly increased if a mixture of organisms was intravenously injected. It was possible that in human pyelocystitis there was a double infection and the second one was overlooked.

Dr. Charles Hunter Dunn of Boston related a case in which a baby had an empyema and aspiration of the chest showed a pure pneumococcus infection. A blood culture was taken and this showed no pneumococci but a pure culture of colon bacilli. Two days later the child developed a typical pyelocystitis. Dr. Dunn said that formerly he had not believed in infection through the hematogenous route in pyelocystitis, but he was now coming to believe in the possibility of infection through this route.

Dr. William Palmer Lucas of San Francisco said they had been making similar experiments, and their results had been similar to those of Dr. Helmholz. He felt that they were warranted in thinking that there was no definite localization in the kidney, but a general infection by which any organ might become involved.

Dr. Henry Heiman of New York said that if we accepted the theory that pyelocystitis was a hematogenous infection involving other organs as well as the kidneys and that the colon bacillus was the predominating organism, then we had a problem to solve. It would seem that the pelvis of the kidney was more readily infected through the urethra. Of the cases in which the pelvis of the kidney was infected 75 per cent. occurred in girls in whom infection through the urethra occurred more readily than in boys.

Dr. Henry M. Helmholz, in closing, said he was much interested in the case reported by Dr. Dunn. It had been his experience that if other organisms were present that might have caused the pyelocystitis, one might not find them, but usually found a member of the colon group, because the colon bacillus had a tendency to overgrow other bacilli. Personally he said he saw no reason to believe that the kidney might not be infected in a number of ways.

Tuesday, May 29—Second Day.

A Case of Precocious Menstruation. — Dr. William Palmer Lucas of San Francisco reported this case. He said the case might equally as well have been reported as one of linear nævus. This girl when first seen was nineteen months of age and gave a perfectly negative family history. Her first menstruation started when she was fifteen months old. Physical examination showed a raised linear lesion between the nose and lip on the left side. It was yellowish in color, verging on a brown, and resembled a keratitic condition. The child had well-developed mammæ and a somewhat advanced development of the small bones. Psychologically her intelligence was normal, but the faculty of attention was phenomenal. She did systematically things that would have been difficult for a child three or four years of age to do.

Dr. Howard C. Carpenter of Philadelphia called attention to the fact that some cases of polypoid sarcoma of the vagina in children had been reported in which there was a certain amount of hemorrhage. Before making a diagnosis of precocious menstruation the possibility of neoplasm must be carefully looked into.

A Case of Hemorrhagic Disease in the Newborn Treated by Direct Transfusion.—Dr. J. H. Mason Knox of Baltimore reported this case. He said that on March 6 he was called to see an infant two days old because it had vomited a considerable amount of bloody fluid. The family history was unimportant. The child weighed seven pounds six ounces. It showed no fever or cough, and nothing abnormal could be made out. During the examination it passed from three to five ounces of tarry-stained material, evidently a hemorrhage from the intestinal tract. The condition was diagnosed as melena, and 50 c.c. of the mother's blood was transfused. Fifteen c.c. of the blood was citrated and introduced into the longitudinal sinus. The remainder was administered intramuscularly into the buttocks. From 9 A. M. to 3 P. M. the child passed several tarry stools, became greatly blanched, the pulse became thready, and respiration shallow. Later the child began to improve. The following day there was one hemorrhage from the bowels, not accompanied by any change in the pulse or temperature. From this time on the child made an uninterrupted recovery.

Dr. Fritz B. Talbot of Boston said that one of the interesting features in these cases was that they frequently had a high temperature at some stage of the disease. In certain instances in which the hemorrhage was under the scalp or into the muscles he wondered whether the rise in temperature could be due to the absorption of the hemorrhage.

Dr. Alfred F. Hess of New York said that to his mind direct transfusion was the method of choice in these cases. He believed that direct transfusion was better than citrated whole blood. He believed that final investigations showed that citrated blood was not the same as whole blood.

Dr. Henry E. Helmholz of Evanston, Ill., said that most of these cases would recover without direct transfusion. They could be cured by intramuscular injections of whole blood, which could be given in amounts up to 100 c.c.

Dr. Charles Gilmore Kerley of New York said that he had had three cases of hemorrhagic disease in the

newborn within half a year which were entirely relieved by intramuscular injection. One-half ounce of blood injected into each buttock stopped the bleeding just as effectually as the use of the serum by the Welch method.

Dr. La Fetra of New York said that ever since Dr. Schloss had published his method of giving the intramuscular injections of whole blood he had been using this method. They had used it in some fifty cases, making the injection into the loose tissue in the scapular region. One did not have to use large quantities of blood; it was more important that the injections be made at frequent intervals. If human blood could not be obtained horse serum might be used.

Skiagraph of a Case of Idiopathic Dilatation of the Colon.—Dr. J. P. Crozer Griffith of Philadelphia presented this skiagraph. He said that the subject was a little boy four years of age. The *x*-ray showed marked peristalsis and an enormously dilated colon. It was with difficulty that he had been able to stay the hand of the surgeon. As the child's condition was fairly good he thought it better to treat him medically than to shorten the colon. Under the use of pituitrin and dietetic measures the boy's condition had improved. He believed that a resection of the colon was the proper procedure when the patient's condition was serious, but he had stayed the hand of the surgeon in some cases in which the condition was an acquired one and had seen the patients get well without operation. One must distinguish idiopathic dilatation of the colon from pyloric stenosis.

Dr. Fritz B. Talbot of Boston said that all were aware of the poor results of surgery in these cases. They had been using a well-fitting elastic belt that compressed the lower abdomen and had had encouraging results.

Dr. L. Emmett Holt of New York called attention to the necessity of distinguishing between Hirschsprung's disease and marked intestinal indigestion. He thought that in the mind of the general practitioner these two conditions in children were often confounded. The surgeon frequently made the mistake of operating on a case simply because the *x*-ray showed a dilated colon. In many cases an elastic band gave the needed support to a thin abdominal wall. In cases in which there were no signs of ulceration and the child was in fair condition the indications were to stay the hand of the surgeon, since a good many of these cases would get well under medical treatment even when the distention was very great.

Three Children with Sporadic Cretinism in One Family.—Dr. Charles Herrman of New York made this report. He stated that this was the second opportunity he had had of presenting three cases of sporadic cretinism in one family. The first series of cases had been reported in the *New York State Medical Journal*, August, 1914. The three patients in the present series were twenty-two, twenty, and eighteen years respectively, and had been under treatment intermittently since they were three years old. The mother had been pregnant twelve times, and these cretins were the third, fourth, and sixth births. The ninth and tenth pregnancies miscarried. It was noticed at the age of two years that these children were not developing properly mentally and physically. At the age of three years they were taken to Johns Hopkins Hospital, where they were treated intermittently for several years. The older girl began to menstruate at the age of seventeen, the younger at the age of fifteen. They came under the writer's observation in March, 1917, at which time their mental and physical condition was greatly retarded. The general appearance of the children was that of cretins who had been under treatment intermittently. They had now been under treatment for two and one-half months with a combination of extracts of thyroid, pituitary and suprarenal glands, and shown marked improvement both mentally and physically. It seemed very unlikely that either constitutional disease, such as syphilis, tuberculosis, or malaria, was responsible for the condition; neither did consanguinity seem to explain the condition. It seemed to the author that anomalies of the ductless glands could best be explained on the basis of heredity. The defect was not necessarily of the thyroid. Family pedigrees were usually incomplete or inaccurate, and it did not follow that because one could not elicit a history of such a defect therefore none existed.

Dr. John Ruhrah of Baltimore asked Dr. Herrman if he had ever seen a case of cretinism that remained perfectly normal in adult life.

Dr. Godfrey R. Pisek of New York said he did not think these cretins were ever cured or ever got beyond the moron stage. They had to be kept under thyoid treatment for years.

Dr. Henry Heiman recalled a case of cretinism that had been under his observation for years. He said they were obliged to give this patient thyroid after he was apparently well. He had gone through school and high school, had reached a height of five feet ten inches, and was a bookbinder. In these cases the after treatment always had to be continued.

Dr. J. P. Sedgwick reported that they had had a case of congenital cretinism last winter. He said he was interested in knowing whether congenital cases were common and whether the rest of the members had seen them.

Dr. Charles Herrman, in closing, said that the results of treatment depended upon how early treatment was instituted. Some of these cretins reached a normal standard physically but never mentally. However, they might become near enough normal to go into business and to get through life fairly well.

The Restoration of Maternal Nursing after Sixteen Days of Complete Interruption.—Dr. Thomas S. Southworth of New York reported this case. He stated that this child on the ninth day after birth developed a severe cellulitis as the result of a birth injury, which involved the right buttock, the entire lower part of the back from the ribs to the sacrum, the under surface of the chin, and the upper part of the neck. There was also a profusely suppurating otitis media the result of a birth injury. Owing to the erysipeloid appearance of the cellulitis about the chin, the baby was removed from the breast and the mother allowed to return home. The mother made no attempt to pump her breast or retain her milk. Two weeks after she returned home it seemed probable that if the baby did not receive breast milk it would die, so it was decided to take the baby home. The mother began by taking a pint of cornmeal gruel and one quart of milk daily, following definite instructions. At first complementary feedings of malt soup mixture were given after each nursing. After a few days these were stopped and the breast milk sufficed. From this time on the infant's progress was slow but fairly continuous, and he gradually overcame his various infections. While the restoration of the breast milk after an interruption of sixteen days was not so remarkable, it was well that we should be reminded of its possibility. The measures adopted to this end undoubtedly played some part in the success of the effort.

Dr. Charles Herrman of New York said he had a chart that demonstrated the possibility of resuming breast feeding after an interval of ten weeks. It was important to remember that in mothers who had stopped breast feeding it could be resumed if a persistent effort was made.

Dr. J. P. Sedgwick of Minneapolis said he wished to endorse Dr. Southworth's remark that it was well to be reminded of the possibility of resuming breast feeding when it had been interrupted. This was one of the most important things in pediatric and general practice. Dr. Sedgwick related an instance in which breast feeding had been resumed after an interval of nine weeks, and said that cases had been reported in which breast feeding had been resumed after an interval of three or four months.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Connecticut.

March 13 and 14, 1917.

ANATOMY AND HISTOLOGY.

1. Describe the elbow joint.
2. Describe the minute anatomy of the pancreas.
3. Give the attachments, action, and nerve supply of the following muscles—digastric, biceps femoris, soleus, gastrocnemius.

4. Describe the occipital bone.
5. Give the anatomical relations of the axillary artery.
6. Describe and give the relations of the prostate gland.
7. Describe the minute anatomy of the female breast.
8. Describe the origin, course, and distribution of the internal mammary artery.
9. Describe the course and distribution of the musculo-spiral nerve.
10. Give anatomical relations of the common bile duct.

PHYSIOLOGY.

1. Discuss the functions of the cerebellum.
2. What important centers are located in the medulla oblongata?
3. How does the eye accommodate for objects at different distances?
4. Name the substances necessary for the formation of fibrin in blood clot. From what substances are they derived?
5. How is the flow of venous blood to the heart influenced by inspiration? Why does the flow of blood in the arteries remain unaffected?
6. Discuss the function of the parathyroid glands.
7. (*a*) How do smooth muscle fibers differ from striated muscle fibers in their reaction to stimuli? (*b*) Under normal conditions what chemical changes occur in the muscle as a result of contraction?
8. Discuss the exchange of oxygen and carbon dioxide in the tissues.
9. Name three enzymes that act on carbohydrates.
10. Where is trypsin formed? On which group of foods does it act?

MATERIA MEDICA AND THERAPEUTICS.

1. Discuss the treatment of hemorrhagic disease of the new born.
2. (*a*) Name the drugs used to cause an increase in the flow of urine. (*b*) Discuss the use of diuretics in acute nephritis.
3. Discuss the treatment of summer diarrhea in infants. State the dose of any drug you might use.
4. Name the preparations of mercury used in the treatment of syphilis, stating the dose and method of administration of each.
5. What are the symptoms and signs of mercurialism?
6. (*a*) What are the chemical properties of chloral hydrate? (*b*) What effect has it on (1) the central nervous system; (2) the heart? (*c*) What is the usual dose for an adult?
7. Write a prescription containing two bitter tonics commonly used to increase gastric secretion.
8. What are the symptoms and signs of digitalis poisoning, following prolonged therapeutic doses of the drug?
9. Name the three most important drugs of the digitalis group.
10. What drugs would you use for the immediate relief of an acute attack of asthma? State the dose and method of administration of each drug.

HYGIENE AND MEDICAL CHEMISTRY.

1. State the reasons that tend to create military inefficiency, "in the field," in a body of men not physically fit when mustered in.
2 and 3. What precautions should one use in selecting a recruit? (State minutely.)
4. What fabrics are warm for cold and windy weather? State reasons.
5. What are the conditions that a military hygienist should consider in the selection of a camp site?
6 and 7. State how you would arrange for the housing of a thousand men in a camp of instruction, there being only unmatched lumber and soldier labor. The camp is in this latitude and the season March.
8 and 9. As a sanitary inspector what recommendations would you make to prevent the spread of the following diseases? (*a*) Typhoid, (*b*) typhus, (*c*) yellow fever, (*d*) malaria, (*e*) syphilis.
10. (*a*) Is there any way by which the ordinary soldier can distinguish good from dangerous water? (*b*) What means are commonly at his disposal by which he can render germ laden water safe? (*c*) What chemical means of rendering this dangerous water potable is at the disposal of the hygienist?

ANSWERS.

ANATOMY AND HISTOLOGY.

1. The *elbow-joint* "is a ginglymoid articulation formed above by the lower extremity of humerus, below by upper extremities of ulna and radius. Its ligaments are external and internal lateral, anterior and posterior ligaments. *External lateral* arises from external condyle of humerus and is inserted into outer margin of ulna. *Internal lateral*, much stronger, consists of two portions; *anterior* arises from fore part of internal condyle to be inserted into coronoid process, and *posterior* from back part of condyle to inner margin of olecranon. *Anterior* ligament arises above coronoid fossa, and is inserted into coronoid process of ulna and orbicular ligament. *Posterior ligament*, attached above olecranon fossa, and below to olecranon process of ulna. The anterior and posterior ligaments become continuous with the lateral to encircle the joint."—(Young's *Anatomy.*)

2. *Minute anatomy of the pancreas:* "The *pancreas* consists for the most part of long tubular acini of columnar or polygonal epithelial cells, supported by very loose fibrous tisue. The cells are of the serum-secreting type. Their inner portion shows granules; the outer part is clearer, and sometimes striped. The pancreas has, therefore, a general resemblance to the parotid gland, but differs from it in two respects: (1) The intralobular ducts are lined by flat epithelium, and are inconspicuous; (2) between the acini here and there are islands of epithelial cells without any glandular arrangement. These are the *islets of Langerhans.* In some of the acini, close to the lumen, stellate cells can be seen. These are the *centroacinar cells of Langerhans*, and are probably continued into the acini from the small ducts. There are spaces between the cells continuous with the lumen of the acini. The larger ducts are lined with columnar epithelium, with a few goblet cells here and there, and the largest ducts have a ring of non-striped muscles in the fibrous wall. Numerous nerve fibers with nerve cells in their course run through the pancreas and end among the cells. Some of them may terminate in Pacinian corpuscles."—(*Aids to Histology.*)

3. DIGASTRIC. *Origin:* Groove on internal surface of mastoid process, and from posterior surface of body of inferior maxilla, near the symphysis. *Insertion:* Tendon attached to hyoid bone by a process of the deep cervical fascia. *Action:* It depresses the lower jaw and raises the hyoid bone. *Nerve supply:* Mylohyoid branch of inferior dental nerve and facial nerve.

BICEPS FEMORIS. *Origin:* Tuberosity of the ischium, great sacrosciatic ligament, outer lip of linea aspera of femur, upper part of line to external condyle, and intermuscular septum. *Insertion:* Outer side of head of fibula, by two slips. *Action:* Flexes knee, extends thigh, and rotates leg outward. *Nerve supply:* Great sciatic.

SOLEUS. *Origin:* Posterior surface of head of fibula and upper part of posterior surface of shaft of fibula, and oblique line and middle part of internal border of tibia. *Insertion:* By tendo Achillis into posterior part of os calcis. *Action:* It extends the ankle. *Nerve Supply:* Internal popliteal and posterior tibial.

GASTROCNEMIUS. *Origin:* Posterior part of inner condyle of femur and line above it, and posterior part of outer condyle. *Insertion:* By tendo Achillis into posterior surface of os calcis. *Action:* It flexes the knee and extends the ankle. *Nerve supply:* Internal popliteal.

4. The *occipital bone* forms the posterior inferior portion of the cranium. It presents two surfaces, four angles, and four borders. The external and posterior surface is irregularly convex and presents: The occipital protuberance for insertion of ligamentum nuchæ, and descending from which to the foramen magnum is the occipital crest; on either side, above and below are the superior and inferior curved lines for the attachment of muscles. In front it presents a large aperture,

the *foramen magnum*, transmitting the medulla oblongata and its coverings, the vertebral arteries, and the spinal accessory nerves. A little in front and on either side of the foramen magnum are the condyles for articulation with the atlas, the inner border of each condyle presenting a *tubercle* for the check ligament. Externally to each condyle are the *jugular processes*. In front of the foramen magnum is the *basilar process*, articulating with the sphenoid bone, and grooved on its under surface by the *pharyngeal spine* for the insertion of the tendinous raphé and superior constrictor of the pharynx. The *internal surface* is irregularly concave and divided by a *crucial ridge*, into four fossæ, the upper, for the posterior lobes of the cerebrum, and the lower, for the lateral lobes of the cerebellum. Its center is marked by an eminence, the *internal occipital protuberance*, which is hollowed out to correspond to the *torcular Herophili*. The upper division of the crucial ridge affords attachment for the falx cerebri, being grooved for the great longitudinal sinus; the lower extremity affords attachment for the falx cerebelli, being grooved for the occipital sinus; and the lateral divisions afford attachment for the tentorium cerebelli and are grooved for the lateral sinuses. In front of the foramen magnum is the basilar groove, lodging the medulla oblongata and part of the pons Varolii. The *superior angle* articulates with the parietal bones, the *inferior angle* articulates with the sphenoid, and the *lateral angles* are wedged in between the mastoid portion of the temporal and the posterior inferior angle of the parietal.—(Young's *Anatomy.*)

5. Relations of Axillary Artery. *In front:* Skin; fascia; pectoralis major and minor; costo-coracoid membrane; external anterior thoracic, inner head of median and internal cutaneous nerves; cephalic and acromiothoracic veins. *Behind:* First intercostal, serratus magnus, subscapularis, and tendons of latissimus dorsi and teres major muscles; posterior thoracic, internal anterior thoracic, musculospiral, and circumflex nerves, also posterior cord of brachial plexus. *Outer side:* Coracobrachialis; brachial plexus, and median and musculocutaneous nerves. *Inner side:* Axillary vein; ulnar, lesser internal cutaneous, and internal anterior thoracic nerves, and inner cord of brachial plexus.

6. *Prostate gland* is about 1½ x ¾ x ½ inches, and weighs about three-quarters of an ounce. It resembles a chestnut in size and form. It is situated at the neck of the bladder, and surrounds the first part of the urethra. It consists of fibromuscular (unstriated) tissue with imbedded follicular pouches, the whole enclosed in a firm fibrous capsular continuous in front with the triangular ligament, and behind with the posterior layer of the deep perineal fascia. The gland consists of three lobes, two lateral and one middle, and is perforated from base to apex by the urethra. The common seminal ducts open into the prostatic portion of the urethra, and are placed between the middle and lateral lobes.

Relations. *Anteriorly:* Symphysis pubis, anterior ligaments of bladder, branches of dorsal vein of penis. *Posteriorly:* Rectum. *Laterally:* Levator ani. *Base:* Surrounds neck of bladder, seminal vesicles, and vasa deferentia. The *apex* rests on triangular ligament.

7. "The mammary gland is a multiple alveolotubular organ. It is composed of from fifteen to twenty individual compound glands. Each of these possesses its own excretory duct, that has its own opening in the nipple. The entire organ is covered by skin. Each gland consists of lobes and lobules separated and supported by white fibrous and adipose tissues. All of the individual glands are further bound together in the same manner. The ducts converge and end in the nipple, which forms a small projecting mass. Each lobule consists of a number of acini which are tubular or alveolar in structure. The number of these depends upon the state of activity. In the gland of pregnancy, the acini are very numerous, and are lined by simple columnar or cuboidal cells, in which are accumulated the fat globules that form the important constituent of the milk. These cells rest upon a basement membrane, but in places are separated therefrom by peculiar elements called basket cells, which are compared to the smooth muscle tissue of the sweat glands. The ducts are lined by simple columnar cells which rest upon a basement membrane, outside of which circular bundles of white fibrous tissue are to be found. These ducts unite to form the main secretory duct of the individual glands; each main duct dilates to form a small ampulla or sinus lactiferus, before the nipple is reached."—(Radasch's *Compend of Histology.*)

8. The *internal mammary artery* arises from the under surface of the first part of the subclavian; it passes downward behind the clavicle and the subclavian vein to the posterior surface of the first costal cartilage, then between the pleura and the costal cartilages as far as the sixth space; it lies on the triangularis sterni muscle, and at the sixth space it divides into its two terminal branches, the musculophrenic and superior epigastric. Its other branches are the cornes nervi phrenici, mediastinal, pericardiac, sternal, anterior intercostal and perforating. It is distributed to the diaphragm, anterior mediastinum, thymus, pericardium, triangularis sterni, sternum, intercostal spaces, pectoral muscles, mammary gland, and rectus abdominis muscle.

9. The *musculospiral nerve* is derived from the posterior cord of the brachial plexus, and originates from the sixth, seventh, and eighth cranial nerves. At first it is behind the axillary and brachial arteries; it winds around the humerus in the musculospiral groove with the superior profunda artery; it pierces the triceps muscle. At the elbow joint it divides into the radial and posterior interosseous nerves. It supplies the triceps, anconeus, supinator longus, brachialis anticus, and extensor carpi radialis longi muscles.

10. The *common bile duct* passes along the right border of the lesser omentum, behind the first part of the duodenum, in front of the portal vein and to the right of the hepatic artery; it then passes between the pancreas and duodenum, in front of the inferior vena cava, and enters the small intestine by an opening common to it and the pancreatic duct.

PHYSIOLOGY.

1. *Functions of the cerebellum.* "When the normal impulses from the cerebellum are wanting, there is defective coordination of muscular movements as well as defective muscle tone. As a result, the power of maintaining the equilibrium of the body is impaired and the gait is staggering, though consciousness and volition are not affected. Further, observation of the results of localized lesions shows that different areas of the cerebellar cortex are associated with different groups of muscles, although no histological difference can be detected in the various parts of the cerebellar cortex. The cerebellum is, therefore, a reflex center for the maintenance of muscle tone and for the coordination of muscular movements. It is especially concerned with the maintenance of the position of the body in relation to gravity, and with coordination of the body as a whole."—(Bainbridge and Menzies's *Essentials of Physiology.*)

2. *Centers located in the medulla oblongata* are those for respiration, salivary secretion, mastication, sucking, deglutition, vomiting, voice, facial expression; it also contains the cardiac and vasomotor centers.

3. *Mechanism of accommodation.* "The lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle (especially the circular fibers) contracts, drawing forward the choroid and relaxing the suspensory ligament; this diminishes the tension of the lens capsule and allows the inherent elasticity of the lens to increase its convexity. The change in curvature affects chiefly the anterior surface of the lens. This is Helmholtz's theory and the one usually accepted. Lately Tscherning has advanced a different theory; he maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction and that this causes peripheral flattening of the lens with bulging anteriorly at its center. The act of accommodation is accompanied by contraction of the pupil, and (in binocular vision) by convergence of the visual lines."—(May's *Diseases of the Eye.*)

4. The formation of fibrin in the process of blood clotting is due to the interaction of fibrinogen and thrombin. Thrombin is derived from thrombogen by the action on the latter of salts of calcium.

5. During inspiration the venous flow to the heart is

assisted by the aspiratory action of the thorax; the negative pressure in the thorax becomes more negative and the venous blood is drawn into the thorax and toward the heart. This negative pressure hardly affects the aorta, and so the flow in the arteries is not affected.

6. *Removal of all the parathyroids* causes death from acute tetany. Their exact function is unknown, but it is supposed that some of the evil effects attributed to removal of the thyroids is really due to the removal of all the parathyroids as well, and that if the parathyroids are left (with their blood supply intact) these results will not ensue. The parathyroids are also concerned in the calcium metabolism of the body.

7. The contractions in *non-straited, involuntary muscles* are not under the control of the will; they are rhythmical, and are characterized by peristalsis. Example, the muscles in the walls of the intestines. In *striated, voluntary muscles,* the contractions are largely under the control of the will, are not rhythmical, and are not characterized by peristalsis. Example, the flexor muscles of the forearm.

When a muscle is in a state of activity: (1) It becomes shorter and thicker, but (2) there is no change in volume; (3) there is an increased consumption of oxygen; (4) more carbon dioxide is set free; (5) sarcolactic acid is produced; and hence (6) the muscle becomes acid in reaction; (7) it becomes more extensible, and (8) less elastic; (9) there is an increase in heat production and consequently a rise of temperature; (10) the electrical reaction becomes relatively negative; and (11) a sound is produced.

8. "Oxygen passes from the blood to the tissues by diffusion, and the amount which is available for the tissues depends largely upon the extent to which oxygen is set free in the plasma by the dissociation of oxyhemoglobin. If the tension in the tissues were zero, as was formerly supposed, the conditions during the passage of blood through the capillaries would be the same as if it were exposed to a vacuum, and the dissociation of oxyhemoglobin would be almost complete. Recent observations have shown, however, that the actual tension of oxygen in the tissues varies from 10 to 40 mm. of mercury, being highest in the glandular tissues and least in the muscles; this tension is so low that, as the blood traverses the capillaries, its oxyhemoglobin undergoes dissociation to a considerable extent. The oxygen thus set free passes into solution in the blood plasma and diffuses into the tissues. Further the rate at which oxyhemoglobin dissociates at this tension is increased by the addition to the blood of carbonic acid, and often of lactic acid, as it passes through the capillaries. In addition to these two factors, the amount of oxygen available for the use of the tissues depends upon the rate at which the blood is flowing through the capillaries. Carbonic acid also passes by diffusion from the tissues, in which its tension is high, into the plasma, in which its tension is much lower. The tension of carbonic acid in the tissues is ascertained indirectly by measuring its tension in bile or urine, and is about 8 or 9 per cent. of an atmosphere, whereas its tension in blood is only 5 to 6 per cent. of an atmosphere."—(Bainbridge and Menzies's *Essentials of Physiology.*)

9. *Three enzymes that act on carbohydrates:* Ptyalin, amylopsin, and maltase.

10. *Trypsin* is formed in the pancreatic juice; it acts on proteins.

MATERIA MEDICA AND THERAPEUTICS.

1. *Treatment of hemorrhagic disease of the newborn.* "By far the most satisfactory method of treatment is by the use of fresh human blood. The simplest and most satisfactory method is to withdraw from the arm of one of the parents, or other suitable individual, 30 to 50 c.c. and inject it subcutaneously or intramuscularly into the patient. This may readily be accomplished by using a relatively large syringe which holds, say, 20 c.c. By having two needles, leaving one in the vein when the syringe is filled, and using the other to inject the infant, it becomes feasible to easily and rapidly administer the treatment. The child should be reinjected every four to eight hours, depending upon the behavior of bleeding. This injection should be continued for one to two days or longer if the tendency to hemorrhage persists. Another simple procedure is to use an anticoagulant, the best of which is sodium citrate, in about 0.2 per cent. solution. This method has the advantage of permitting more time in the procedure, as there is no danger of the blood clotting. Another point in its favor is that a large amount, say 200 c.c., may be drawn from the donor into a citrate solution, and if kept cool will remain active for a week, and can be injected subcutaneously or intramuscularly in doses of 30 to 50 c.c. every four to eight hours. The use of the fresh or citrated blood, on account of the ease and rapidity of its application, will as a rule take preference over the direct transfusion. Where the infant is exsanguinated, direct transfusion may be desirable. The use of fresh animal serum or the dried precipitated sera is much less desirable than fresh human blood on account of the danger of anaphylactic reaction and inactivity of the preparation used. The use of supposed coagulants, as calcium chloride or gelatin, which at most are of questionable value since the use of fresh blood, can be dispensed with. Especially should the physician avoid wasting valuable time by trying these remedies first, rather than resorting at once to the use of fresh blood.—(Musser and Kelly's *Practical Treatment.*)

2. *Drugs used to cause an increase in the flow of urine:* Potassium acetate, bitartrate, and citrate; sodium acetate; ammonium acetate; lithium citrate and carbonate; magnesium citrate and sulphate; water; milk; digitalis; strophanthus; convallaria; squill; sparteine; calomel; caffeine; the nitrites; alcohol; cantharides; juniper; buchu; uva ursi.

"There is much difference of opinion as to *the use of diuretics in acute nephritis.* Some observers believe that all diuretics are irritating to the kidneys and therefore should be withheld at least during the stage of engorgement. Most authorities admit, however, that mild alkaline diuretics, like the vegetable salts of potassium, often serve a useful purpose in removing from the uriniferous tubules proliferated epithelium, albuminous plugs, and effete matter. From 20 to 30 grains of the citrate or acetate of potassium may be given three or four times a day, well diluted. Later in the disease, when the pulse tension falls, experience has proved that digitalis is often of great value. From 2 to 4 fluid drams should be given every three or four hours. It may be combined advantageously with an alkaline diuretic."—(Stevens' *Materia Medica and Therapeutics.*)

3. *Treatment of summer diarrhea in infants:* "Hygiene should be improved and exposure prevented. Feeding should be corrected. Cleanliness is imperative. Woolen clothing should be worn next to the skin when there is susceptibility to changes in the atmosphere. During the attack all food should be withheld for from twelve to thirty-six hours, and the child placed in bed. The thirst may be quenched by water, ice, barley-water, etc. If the child is weak brandy, gtt. 10-15, may be given. For the abdominal pain warm baths, turpentine stupes, spice poultice, and mustard plaster may be necessary. When food is given again it must be weak and in small quantities. The alimentary canal should be cleared of all irritating material by syrup of ipecacuanha, 51, if the stomach contains food, or by castor oil, equal parts of castor oil and aromatic syrup of rhubarb, 51 every hour until free bowel movement, or calomel, gr. ½, with soda bicarbonate, gr. 1, for four or five doses. The colon should be irrigated once or twice daily. If improvement is not marked in from twenty-four to thirty-six hours intestinal antiseptics, astringents, or both may be administered."—(*Pocket Cyclopedia.*)

4. In the treatment of syphilis, mercury may be administered: (1) *By the mouth:* Hydrargyri iodidum flavum, gr. 1/6 to 1; hydrargyum cum creta, gr. 1 to 2; hydrargyri chloridium corrosivum, gr. 1/12; each of these doses should be given three times a day. (2) *By inunction:* Unguentum hydrargyri, 2 to 4 drams every night on a different part of the skin. (3) *By intramuscular injection:* Calomel, gr. 1 or 2 in sterilized olive oil; or oleum cinereum, 1 dram; or mercuric salicylate, 1 c.c. of 10 per cent. suspension in oil. (4) Other methods include intravenous injections, spinal injections of mercurialized serum, inhalations of mercury or calomel vapor, fumigation, and plasters.

5. *Symptoms and signs of mercurialism:* Sore teeth,

spongy gums, profuse salivation, fetid breath, bluish line on the gums along the margins of the teeth, swelling of the salivary glands, aching of the jaws, fever, emaciation, anemia, diarrhea, cachexia, and malnutrition.

6. *Choral hydrate* is a compound of trichloraldehyde and a molecule of water. It is soluble in water, is neutral in reaction, has an ethereal odor, a sharp taste, and is easily decomposed under the influence of sunlight and potassium chlorate. On the *central nervous system* it acts as a hypnotic; it depresses and paralyzes the nervous system. It depresses the *heart*, and causes dilatation of both auries and ventricles. The usual adult dose is about 8 or 10 grains.

7. ℞.

Acidi nitrohydrochlorici diluti ℥vj.
Tincturæ aurantii amari.
Tincturæ calumbæ āā ℥j.
Infusi gentianæ q. s. ad ℥x. M.

Sig. One tablespoonful in a wineglassful of water, after each meal.

8. *Prolonged therapeutic doses of digitali: may cause:* Weak, dicrotic pulse, perspiration, nausea, vomiting, lowered reflexes, lowered body temperature, vertigo, muscular tremors, lassitude, delirium, stupor.

9. Digitalis, strophanthus, and convallaria.

10. For an *acute attack of asthma*, the following have been used: The fumes of ignited stramonium or belladonna leaves which have been steeped in potassium nitrate; these drugs may be burned in the patient's room, or smoked as cigarettes. Amyl nitrite, 5 to 6 minims, by inhalation; or a few whiffs of chloroform. Adrenalin solution (1:5000) on a pledget of cotton applied to the nasal mucous membrane or sprayed on to it. A hypodermic of morphine sulphate, ⅛ of a grain. Heroin hydrochloride, hypodermically, in 1/12 grain doses. Inhalation of compressed air or oxygen.

Hygiene and Medical Chemistry

1. The men may be suffering from various inherited defects; or from diseases due to accident or injury, or to the effects of climate, or to bad habits and modes of life (such as venereal diseases, and alcoholism); or to diseases such as typhoid, cholera, malaria, dysentery, etc. Improper food, clothing, hardships, and overcrowding are also factors. Any diseased condition of heart, blood vessels, nerves, lungs, abdominal organs, joints, feet, etc., may also cause inefficiency.

2. and 3. The following extracts are from the regulations prepared by the Surgeon-General of the Army:

The physical examination should take place in a large, well-lighted room. The person examined is to be stripped. The examining physician should proceed in substantially the following order, viz:

(*a*) Observe the general condition of the skin, scalp, and cranium, ears, eyes, nose, mouth, face, neck, and chest. Take weight, height, and chest measurements. Accepted measurements are as follows, all chest measurements to be taken on a level just above the nipple:

Height		Weight	Chest Measurement	
			at Expiration	Mobility
Feet	Inches	(Pounds)	(Inches)	(Inches)
5 4/12	64	128	32	2
5 5/12	65	130	32	2
5 6/12	66	132	32½	2
5 7/12	67	134	33	2
5 8/12	68	141	33¼	2½
5 9/12	69	148	33½	2½
5 10/12	70	155	34	2½
5 11/12	71	162	34¼	2½
6	72	169	34¾	3
6 1/12	73	176	35¼	3
6 2/12	74	183	36¼	3
6 3/12	75	190	36¾	3¼
6 4/12	76	197	37¼	3½
6 5/12	77	204	37½	3¾
6 6 12	78	211	38¼	4

To be acceptable, men below 64 inches in height must be of good physique, well developed, and muscular. Variations in weight above the standard are not disqualifying, unless sufficient to constitute obesity. Unless exceptionally well proportioned, men above 6 feet 6 inches in height should be rejected.

(*b*) The arms being extended above the head, backs of hands together, the applicant is required to cough vigorously; any form of rupture may now be discovered by the hand and eye, but still better by the index finger passed up to the external ring.

(*c*) The arms remaining extended above the head, the applicant is required to take a long step forward with the right foot and bend the right knee; the genital organs are now conveniently exposed and varicocele and other defects in the scrotum may be recognized.

(*d*) Arms down and the man required to separate the buttocks with his hands, at the same time bending forward; this exposes the anus.

(*e*) Examine heart and lungs; rate of pulse and respiration.

(*f*) Upper extremities: Make sure that all joints are free and supple, from the phalanges to the shoulder.

(*g*) Lower extremities. The person under examination is required to leap directly up, striking the buttocks with the heels, to hop the length of the room on the ball of first one foot and then the other, to make a standing jump as far as possible and repeat it several times, to run the length of the room in double-time several times, after which his heart and lungs are reexamined.

(*h*) *Mental.*—The mental examination should be such as to develop whether or not the man examined is possessed of normal, sound understanding.

(*i*) *Vision.*—Examine each eye separately, without glasses, covering the other eye with a card (not with the hand). The applicant is directed to read the test types from the top of the chart down as far as he can see, and his acuity of vision recorded for each eye, with the distance of 20 feet as the numerator of a fraction, and the size of the type of the lowest line he can read correctly as the denominator. The minimum visual requirements are as follows: 20/40 for the better eye, and 20/100 for the poorer eye, provided that no organic disease exists in either eye.

(*j*) *Hearing.*—To determine the acuity of hearing, place the applicant facing away from an assistant who is 20 feet distant and direct him to repeat promptly the words spoken by the assistant. If he cannot hear the words at 20 feet, the assistant should approach foot by foot, using the same voice, until the words are repeated correctly. Examine each ear separately, closing the other ear by pressing the tragus firmly against the meatus. The examiner, whose hearing should be normal, faces in the same direction as the candidate and closes one of his own ears in the same way as a control. The assistant should use a low conversational voice (not a whisper), just plainly audible to the examiner, and should use numerals, names of places, or other words or sentences until the condition of the applicant's hearing is evident. The acuity of hearing is expressed in a fraction the numerator of which is the distance in feet at which the words are heard by the candidate and the denominator the distance in feet at which the words are heard by the normal ear; thus 20/20 records normal hearing, 10/20 imperfect hearing, etc. The hearing with both ears open should not be below 10/20.

4. Woolen fabrics are warm for cold and windy weather. Wool is a poor conductor of heat and is not easily penetrated by cold winds. Paper is also a good protective against cold winds, and a paper vest will conserve the warmth of the body.

5. *In selecting a camp site* the following conditions should be borne in mind: The presence of water, wood, and grass. The soil should be dry and elevated, with some protection from winds. There should be space enough to accommodate the men without crowding. Old camp sites should be avoided because the soil is certain to be polluted and may be infected. Excess of vegetation and dense woods should be avoided on account of the extreme moisture or dampness which they induce. Marshes and stagnant water should also be avoided on account of mosquitoes.

6 and 7. "Upon arriving at the selected site, the first duty which concerns the medical officer, if the matter has not been previously attended to, is an examination of the water supply and the determination of the place or places where drinking and cooking water should be drawn. Below this, if the supply is from a stream, other places should be likewise set apart for watering animals, for bathing, and for washing clothing, in the order named." . . . The camp is to be arranged in columns of companies, at convenient distances. Generally the arrangement for each company will be in two lines, facing each other, with

a distance of 15 to 20 yards between the lines; this space forming the company street. From the sanitary point of view the great guiding principle is to separate the kitchen and messes as far as possible from the latrines. Therefore, the rule is to place the kitchen on one flank of the company and the latrine on the other. Near the kitchen is the store tent, and a pit for liquid wastes when cans are not provided for the purpose. Next to the line of kitchens is the line of officers' tents. Plans are prescribed in the Field Service Regulations. (From Havard's Military Hygiene.) The huts may be made to accommodate four to eight men, or barracks may be built to accommodate about one hundred men. According to Smith (quoted in Munson's Military Hygiene), "a space should be cleared for about three feet around the proposed site. The ground to be included should be smoothed and slightly raised, never excavated, and should be pounded or hardened. Trenches should be dug around the huts, and thence in a direction and to the distance required for effective drainage. The ground outside may be slightly raised, but an embankment should never be erected around the bottom for the sake of warmth, but instead the hut may be lined to a convenient height within, to ward off currents of cold air. The cleared space outside should be paved or covered with gravel. Wooden floors should be laid, if possible, and suitable provision made for the entrance of the air from the outside through either the floors or the lower part of the walls. Eaves should carry the rain some distance from the walls and, if possible, porches should be built, as adding much to the comfort of the inhabitants. Ventilation should be secured at ridge, end, and sides." The roofs and outsides may require waterproof sheathing paper; the windows may be fitted with sliding sashes or work on hinges. As a rule, each man should have from 600 to 1000 cubic feet of space, and if the huts or barracks are 10 feet high, this means from 60 to 100 square feet of floor space.

8 and 9. *Typhoid.* Water should be boiled; food must be screened from flies and protected from dust. Those attending the patient must wash their hands with soap and water and with an antiseptic lotion. Protective inoculation is of value to those liable to exposure. The urine and feces must be disinfected; soiled linen or clothing must be kept protected from flies and then boiled before being sent to the laundry. Flies must be kept out of the house. "Carriers" must be avoided.

Typhus. Personal cleanliness is essential; all unnecessary contact with the sick must be avoided, and rubber gloves should be used when attending patients. Cleansing and whitewashing of dark and dirty places should be enforced; sulphur dioxide is a good disinfectant. Quarantine suspected cases. In inhabited houses, phenol is a good disinfectant. Lice and bedbugs, if on the body, should be attacked by mercurial ointment; if in clothing, the latter should be disinfected by steam.

Yellow fever. Destroy the mosquitoes (and their larvæ), or keep them out of the houses. The patient must be isolated in a mosquito-proof room.

Malaria. Destroy the anopheles mosquito. Screen the houses. Persons who have malaria should take quinine regularly.

Syphilis. Notification of the disease, and instruction of the patient. Proper provision should be made for the treatment of genitourinary and venereal diseases. The use of a prophylactic calomel ointment should be advised to those who intend to take risks.

10. A little water should be placed in a large, clean bottle, and then shaken vigorously; if the water is much contaminated an offensive odor will be observed. Germ-laden water should be boiled. The use of chlorinated lime is recommended. Three grains of this substance will purify a barrel of water.

(*To be concluded.*)

Traumatic Syphilitic Gumma.—Lévy and Gaby saw rapidly develop in the site of a contusion a gumma which promptly ulcerated. The patient had contracted syphilis only three months earlier. The gumma, which contained the treponeme, healed promptly under mixed treatment.—*La Presse Médicale.*

INCOMPETENCY OF THE ILEOCECAL VALVE VS. LANE'S KINK AS THE CAUSE OF ILEAC STASIS.

BY J. H. KELLOGG, M.D., LL.D., F.A.C.S.,

BATTLE CREEK, MICHIGAN.

THE significance of the ileocecal valve is clearly shown by an observation of Magnus-Levy in an able article in Von Noorden's compendious work on metabolism. After calling attention to the fact that urobilin, a product of the putrefaction of bile, must be classed with indol, skatol, phenol, cresol, and other poisonous products of intestinal putrefaction, he adds:

"The classic research of Jaffé and Nencki has shown that these bodies are not present in the small intestine, confirmed by A. Schmidt and others. They originate, therefore, in the large intestine, in which the microorganisms have the necessary time to produce abnormal decompositions. This fact has become of importance for the recognition of many intestinal troubles."

In health, according to Weintrand in Von Noorden's Metabolism, urobilin is not found in the small intestine; it first appears in the cecum and ascending colon. (Nencki and Sieber, Macfadyen, A. Schmidt, Schlorlemmer.) Since the conditions in the colon are unfavorable to absorption, urobilin seems thus to do little harm so long as it is confined to the first part of the large intestine where it is produced. *But when the ileocecal valve,* which forms a sharp line of demarcation (A. Schmidt), is incompetent, the urobilin is forced back into the small intestine, and is there quickly absorbed along with other poisons.

It appears, then, that the ileocecal valve is the chief barrier against the flooding of the body with the multitudinous toxins which are generated in the colon. So long as the putrefaction products are confined to the colon they do comparatively little harm because of the slow rate of absorption; but when they are carried by reflux into the small intestines they are rapidly absorbed, and the result is an attack of headache, so-called "biliousness," a skin eruption, loss of appetite, depression, or some other indication of a toxemic state.

The condition most favorable to the development of intestinal toxemia is ileac stasis, as originally pointed out by Arbuthnot Lane, to whom also the world is profoundly indebted for demonstrating the fact that a very great number of grave chronic ailments are due to the toxemia resulting from ileac stasis, although he erred in his attempt to find the cause of the stasis in certain harmless attachments of the terminal ileum of embryonic origin, commonly known as "Lane's kink."

The association between incompetency of the ileocecal valve and ileac stasis was first definitely established by the thoroughgoing roentgenologic studies of the alimentary canal by the writer's colleague, Dr. J. T. Case. That the relation was one of cause and effect was proven by the writer by operation for repair of the valve and immediate cure of the stasis by so doing. The restoration of the competency of the valve is shown at the operation, and later by a barium enema. The relief of the ileac statis is easily demonstrated by post-operative *x*-ray examination after a barium meal.

It cannot be claimed that incompetency of the ileocecal valve is the one and only cause of ileac stasis. Stasis may be due to obstructive lesions of various sorts; but aside from cases in which the obstruction is complete or nearly so, incompetency of the valve is a far more potent cause of stasis than simple narrowing of the lumen of the small gut. The propulsive efficiency of the small bowel is very great. Food normally enters the intestine in small quantities and the absorptive activity of this part of the alimentary canal is so great that of the 6,000 or 7,000 c. c. of material which enter the bowel every twenty-four hours only a few hundred are left to be sent on into the colon as unusable residue and this small amount is easily passed along by the powerful propulsive peristaltic waves and "rushes" which normally occur in the ileum even though the lumen of the gut may be very considerably narrowed. Every abdominal surgeon of large experience has encountered cases in which constricting lesions of the small intestine were found but in which no evidence of ileac stasis or other disorder in the bowel function has been observed. Adhesions of the small intestine to the abdominal parietes as well as to the intestine itself and other viscera are very common after abdominal operations but very rarely produce stasis.

This fact casts serious doubts upon the importance of the so-called Lane's kink as a cause of stasis. Besides, Case has demonstrated in scores of cases by *x*-ray examination very marked adhesions of the terminal ileum which produced no ileac stasis. In many of these cases the writer has verified the *x*-ray findings at the operating table when operating for removal of a diseased appendix or dealing with some other lesion requiring abdominal section. While the medical profession and the whole world, for that matter, are under great obligations to Sir Arbuthnot Lane for demonstrating the great importance of ileac stasis as a proximal cause of many

of the gravest maladies, it must be admitted that only a comparatively small number of practical surgeons have ever been convinced of the importance of Lane's kink (adhesions of the terminal ileum) as a cause of stasis. And it may be justly added that the disappointing results which have been experienced by most of those who have resorted to short-circuiting and other procedures suggested by Mr. Lane for the relief of stasis have led to a decided and growing skepticism respecting the soundness of his theories relating to the genesis and the significance of adhesions of the terminal ileum, even among those who most admire the wonderful genius and admirable personality of one of the most able and progressive of British surgeons.

Consideration of the ileocecal valve in relation to ileac stasis reveals a very different picture. Here is a brief summary of the facts which have been elucidated by the observations of Bauhin, Kraus, Hertz, Ad. Schmidt, Elliott, Keith, Cannon, Case, the writer, and others:

1. All vertebrate animals, even fishes and reptiles, are provided with an efficient ileocecal valve. The presence of this check valve between the mid-gut and the hind-gut is as universal as the pyloric sphincter between the fore-gut and the mid-gut. The only possible inference to be drawn from this fact is that the ileocecal valve must have an important function to perform, the nature of which though formerly obscure, is now made clear by the researches of Cannon and Elliott in animals and Case, Schwartz and others in *x*-ray studies of the human alimentary canal.

2. A check valve at the junction of the small intestine and the colon is essential for definite and permanent advance of bowel material because of the back pressure due to the normal tonicity of the large gut and the accumulation of material in the colon which normally empties intermittently and not continuously. The check valve is in constant use in engineering practice under similar conditions in steam engines, heating systems, etc. The ileocecal valve is a most admirable illustration of vital mechanics.

3. In addition to the back pressure resulting from the accumulation of gas, liquids, and semi-solids in the colon, additional pressure reacting against the ileocolic junction is induced whenever the bowels move as a result of the contraction of the diaphragm, the abdominal muscles and of the colon itself.

4. Another factor tending to produce reflux from the colon to the small intestine and necessitating intervention of a check valve at the ileocolic junction is found in the periodical contractions of the cecum and ascending colon.

5. A still more powerful factor tending to produce a back flow from the colon into the small intestine and creating an absolute necessity for the function performed by the ileocecal valve is found in the retroperistaltic action of the right half of the colon.

This reversed action of the colon is a powerful movement which starts about the middle of the transverse colon, and forces the intestinal contents back toward the cecum for the purpose of causing delay sufficient to permit the absorption of a considerable portion of the water content of the material sent into the large gut from the small intestine. The action is most vigorous after meals. It was discovered by Cannon in animals, and demonstrated in human beings by Case.

6. The ileocolic valve when normal is a perfect and highly efficient mechanical device. It even works in the dead subject and in the intestine when removed from the body if care is taken to avoid injury to the parts.

7. When the ileocecal valve is incompetent, even slight pressure upon the distended cecum is sufficient to cause reflux of gas and liquid into the ileum.

8. In the living body incompetency of the ileocolic valve is practically always associated with ileac stasis. The incompetency is nearly always demonstrable by the *x*-ray, but sometimes the *x*-ray fails to show the incompetency even when the condition is very marked. There is little or no evidence that spasm of the gut at the ileocolic junction is a frequent cause of ileac stasis.

9. In most cases of incompetency of the ileocecal valve associated with ileac stasis as proven by *x*-ray examinations by Dr. Case and verified by both the writer and Dr. Case at the operating table in connection with various abdominal operations, Lane's kink was absent; that is, no adhesions of the terminal ileum were found in most cases, and in the very small number of cases in which Lane's kink was present the stasis was no greater than in those cases in which adhesions of the terminal ileum were absent.

10. In some scores of cases in which Case was able to show by the *x*-ray the presence of Lane's kink without incompetency of the valve, ileac stasis was present in only two or three cases.

11. Dr. Case, who has observed ileac stasis in several hundred cases, estimates that he finds the stasis due to obstructive adhesions of the terminal ileum in not more than three or four per cent. of all cases of stasis in the small intestine. His observations demonstrate most clearly that the usual cause for ileac stasis is incompetency of the ileocecal valve.

12. It is well known to abdominal surgeons that ileac stasis is rarely if ever cured by the breaking up of adhesions about the terminal ileum. It was this fact which led Sir Arbuthnot Lane to devise the operation of short-circuiting.

13. When incompetency of the ileocecal valve is associated with ileac stasis, the stasis is cured by repair of the valve and without breaking up the adhesions of the terminal ileum when these are present.

14. The relief of symptoms sometimes obtained by the operation of short-circuiting is rarely ever more than temporary. The ileac stasis ultimately returns through the dilatation of the intestine which is inevitable when the newly made ileocolic junction is not protected by a check valve as under normal conditions. The small intestine may be for a short time able to keep itself empty because relieved of the back pressure from the anti-peristaltic action of the transverse colon. But the absence of a barrier against reflux at the ileocolic junction permits the backing up of fecal matters from the pelvic colon after the blind-ended colon has first been filled, and the small intestine is gradually dilated until several

feet of it may become nearly as large as the colon. Case has demonstrated that incompetency of the ileocolic junction and reflux exist in practically all cases of short circuiting performed by Lane's method, which makes no effort to provide the protection of a valve.

15. The writer has demonstrated that the recurrence of ileac stasis after the operation of short-circuiting may be prevented by making an artificial ileocecal valve. I have also succeeded in constructing an efficient valve in cases in which a short-circuiting operation had been previously done by other surgeons without affording relief. This shows that repair of the valve is the curative measure, and not the short-circuiting. (Of course, there are rare cases in which the colon must be sacrificed.)

16. In cases of chronic ileac stasis the walls of the gut are thin and atrophic, evidently the result of degeneration from over work and chronic infection. The lumen of the gut is normal. In stasis due to obstruction, the intestinal wall is inevitably thickened and hypertrophied, while the lumen of the gut is notably increased, showing the effects of forcible distention. This is never seen in intestinal stasis of the ordinary type.

17. The periodic contractions of the cecum alternating with strong retroperistaltic waves starting in the transverse colon, must inevitably cause reflux of the colon contents into the small gut unless movement in this direction is checked by the ileocolic valve. And this action is not occasional but constant for hours after every meal, so that in a person whose ileocolic valve is incompetent, the ileum is seldom if ever empty. Normally the small gut clears itself of a meal within eight or nine hours, thus insuring the gut a period of rest at least during a part of each twenty-four-hour period. When the valve becomes incompetent, the bowel is never empty and hence never at rest. The continued presence of gas and fluid contents keeps the gut perpetually at work. The result is exhaustion and degeneration. Another potent cause of degeneration is to be found in the chronic infection which inevitably develops as the result of reflux of putrefying materials from the colon. In the rare cases in which Lane's kink is really the cause of stasis the bowel is found hypertrophied and dilated as in cases in which the lumen of the gut is narrowed to the point of obstruction by ulceration or other causes.

As regards the genesis of obstructive adhesions of the terminal ileum, the writer is fully convinced that they are the natural consequence of incompetency of the ileocecal valve. The constant presence of infectious material from the colon not only causes the terminal ileum to sag down in the pelvis but sets up an enteritis which in time develops into perienteritis and thus causes the gut to adhere to whatever surface it may happen to rest in contact with. The same process is seen in the appendix. Cecal stasis keeps the appendix distended with fecal matter thus causing infection with chronic inflammation and adhesions. The appendix is generally found diseased when the valve is incompetent.

This view is supported not alone by theoretical considerations but by several interesting observations at the operating table in cases in which marked incompetency of the ileocolic valve existed with very pronounced adhesions of the terminal ileum. The disposition of the adhesions was such that *they must have been formed after the valve had become incompetent.* This opinion, shared by my colleagues, Drs. Harris and Case, who assisted at the operations, was based upon the fact that the extensive adhesions involved surfaces which are normally invaginated and lie within the colon and hence must have been pulled out before the adhesions occurred. In fact, the relation of the adhesions to the ileocolic junction was such as to strongly suggest that a very apt and partially successful effort had been made to repair the damaged valve, a most striking illustration of the resources of that marvelous workman, the *vis medicatrix naturæ.*

The ordinary, non-obstructing attachments of the terminal ileum, generally known as Lane's kink, have been clearly shown to be embryonic structures, and without pathological significance.

That incompetency of the ileocecal valve is a true structural lesion and not a mere functional disorder as has been suggested by some internists, will not be questioned by anyone who has taken the trouble to make a careful study of the ileocolic junction either in the anatomical laboratory or at the operating table. Inspection alone is sufficient in most cases to determine whether or not the valve is incompetent. When the valve is competent the ileum is narrowed at its junction with the colon, and its constricted terminus is hidden between folds of the colon. A deep sulcus bridged over by a thin layer of peritoneum is seen on each side of the ileocecal fold.

When the valve is incompetent, the picture is strikingly different. Instead of converging at its junction with the colon, the ileum is widely distended so that the terminus is funnel shaped, diverging toward the colon. The sulcus on either side of Treves's fold is obliterated and the line of junction between colon and ileum which is normally found at the free edges of the two lips of the valve projecting into the lumen of the colon is found upon the surface of the bowel, where it may be easily traced above and below the fold of Treves.

The diameter of the normal ileocolic junction is 2 centimeters. I found the average diameter in 82 cases in which the valve was proved to be incompetent to be 5½ centimeters.

A large amount of gas in the ileum and colon is an almost certain sign of incompetency of the valve. It is easy to test the condition of the valve by making pressure on the gas filled cecum while at the same time compressing the ascending colon.

In operating for repair of incompetency of the ileocecal valve it must be remembered that while the lesion is a direct cause of many serious morbid conditions which grow out of intestinal toxemia, the result of stasis and ascending infection of the small intestine, the lesion itself is a result of some other existing morbid condition. The most common cause is some obstruction existing between the ileocecal valve and the rectum. In many cases the cause will be found in obstructive adhesions of the pelvic or ileac colon. The obstruction is more likely to occur in the middle of the pelvic loop or at the pelvi-rectal junction, but may exist at the ileopelvic junction. Obstruction may also arise from a neoplasm. In a certain number of cases no structural changes are found. In such cases the

cause of obstruction is shown by the *x*-ray to be a spastic condition of the distal portion of the colon, frequently associated with colitis.

Incompetency of the valve may be due to other causes than over-distention of the cecum. Max Hertz called attention to the fact that the valve may become incompetent as a result of tubercular or syphilitic ulceration. The writer has noticed several cases in which the incompetency of the valve seemed to be due to a drag upon the ileocolic junction resulting from adhesions of the terminal ileum to the appendix. In such cases, competency is restored by simply breaking up the adhesions. In several instances the incompetency seemed to be due to adhesions formed subsequent to an operation for removal of the appendix.

Whatever the cause of the incompetency of the valve it must be removed, otherwise the natural result will be a reproduction of the incompetency, for it can hardly be supposed that a repaired valve can be prepared to resist the causes which produce incompetency better than a normal valve. If there are adhesions in the pelvic colon, these must be broken up and measures must be taken to prevent their recurrence. The great extent of these adhesions in some cases renders this complication a difficult one to deal with. Good results have been obtained from the following method:

The pelvic colon is attached to the omentum and the omentum at a point a couple of inches higher up is attached to the abdominal wall. This gives the pelvic colon a swinging attachment which holds it in normal position and prevents reformation of the obstructive adhesions and at the same time does not interfere with the peristaltic movements of the gut and also saves the patient from the inconvenience and pain which frequently result from attachment of the bowel to the abdominal wall.

Obstructions due to Jackson's membrane, adhesions, and bands formed at any point along the colon must be properly dealt with. Tubercular ulcers, cancerous growths, obstructions due to diverticulitis, and other obstructive lesions may require excision of a portion of the bowel.

The interesting facts to which Keith has recently called attention concerning the nodes by which the normal rhythmic function of the intestinal musculature is controlled and organized have little if any bearing upon the subjects discussed in this paper for the reason that the function of the ileocecal valve proper is purely mechanical and hence not influenced by the nervous mechanism which controls the musculature of the small intestine including the *ileocolic sphincter*, which lies above the ileocolic valve and is wholly independent of it in structure and function.

Nature of Acne Rosacea.—Arullani looks upon this as a chronic constitutional affection occurring in subjects with flabby and readily dilatable heart, arterial hypotension (even in youth), cold extremities, hyperidrosis, palpitations, and digestive disturbances, the latter also acting as causes of exacerbations. Much of the treatment which is in use by the general run of practitioners is, he thinks, irrational. The keynote should be increase of vascular tension and improvement of blood count and hemoglobin.—*La Presse Médicale.*

THE DIAGNOSIS AND THERAPY OF CHRONIC INTESTINAL TOXEMIA.*

By GEORGE REESE SATTERLEE, M.D.,

NEW YORK.

Chronic intestinal toxemia is a term that has been loosely employed by many authors, but to those who are constantly studying intestinal conditions, it is a distinct entity and, although not a disease but rather a symptom complex of enteric pathology, it must be treated. Like uremia it is a complex; a poisoning of the system, originating in all probability from definite lesions of the gastrointestinal tract. It is often accompanied by pathological changes in the wall of the gut, usually localized to the right side of the colon. So far, the exact nature of the poison is no more proven than is that of uremia.

It is customary to speak of the toxemias of pregnancy and of nephritis as being of non-bacterial origin and of the toxemias of diphtheria, typhoid, pneumonia and other infectious diseases as being derived from the endo- or ecto-toxins or the end products of bacteria because we know that these diseases are of bacterial origin. The limitations of this paper prevent a detailed discussion of the different theories of chronic intestinal toxemia. The author however is strongly inclined to the view that it can be classed among the bacterial infections. A diseased intestinal mucosa and a metamorphosed colon bacillus, capable of yielding a toxin are essential for this theory.[1]

The diagnosis of chronic intestinal toxemia is based upon three chief factors, the history, the *x*-ray, and the symptomatology and physical signs. The history of these patients begins frequently with an attack of acute indigestion and often a so-called ptomaine poisoning following the ingestion of some easily decomposed or indigestible article of food. This is followed by a prolonged interference with the digestive system and by nervous disturbances, the latter frequently predominating. The primary trouble is probably an intestinal putrefaction, the secondary a chronic intestinal toxemia in which the colon bacillus, metamorphosed, plays the important role due to the toxins liberated.

A brief description of the leading digestive symptoms is as follows:

Constipation.—Constipation may be congenital or acquired, usually the latter, but it frequently follows an abdominal operation. Occasionally a history of constipation is absent and the condition is discovered during radiography of the gastrointestinal tract; it is rarely absent but may be replaced by diarrhea or colitis. In all probability, constipation, recognized or not, has been present and an important factor in the complaint. An alternation of constipation and diarrhea is quite frequent, constipation then being possibly the etiological factor. Evidences of this are the presence of fecal masses in the colon.

Flatulence.—This symptom is nearly always present and is evidenced by eructations and passage of flatus per anum. Abdominal distention may be present, with or without relief by the passage

* Read at the Eighteenth Annual Meeting of The American Therapeutic Society, New York, June 2, 1917.

of gas but when marked and continuous is suggestive of intestinal obstruction. There may be considerable gas production with a soft and flat abdomen. Excess of gas bubble frequently remaining in one spot can be demonstrated in the radiographs. Abdominal pain is one of the results of distention of the gastrointestinal tract and the pain may be out of proportion to the amount of flatus. Kinks and adhesions may confine small amounts of gas and accentuate the pain but we must always consider the nervous susceptibility of the patient. A very common complaint is that "everything turns to gas."

Aerophagia is a frequent complication and can be sometimes demonstrated by fluoroscopy of the esophagus during deglutition. The patient frequently begins to belch and swallow gas immediately on entering the office although perfectly quiet while sitting in the waiting room. Palpitation of the heart results from distention of the cardia. It can be shown by fluoroscopy, the cardia gas bubble pressing up on the heart. A feeling of fullness after the ingestion of small quantities of a meal may be explained on these grounds, for when the gas bubble in the cardia is large it is difficult to make the patient swallow the whole meal. Dr. Aaron[2] finds bile in the stomach contents suggestive of this condition.

Flatulence due to abnormal fermentation or decomposition of carbohydrates may sometimes be distinguished from that caused by decomposition of proteins or putrefaction. The former is characterized by the lack of putrefactive odor to the gas expelled and the latter by the foul odor of the gases due to the formation of the putrescible substances, the phenols, indols, and other nitrogenous decomposition products of protein origin. Carbohydrate free diet will often clear up the former and a meat-protein free diet the latter, but very frequently the two kinds of gas formation are closely associated.

The Nervous System.—The mental symptoms are often far out of proportion to the extent of the lesion. Depression is marked and may even extend into a melancholia. The patient is extremely irritable and disturbed by small things that are usually passed by and the character is often completely changed. He is misunderstood by his family and immediate friends, although he appears normal to his acquaintances. There is lack of concentration and general inefficiency. These defects may lead to obsessions and even to dual personality. Attacks of vertigo, semi or complete unconsciousness, or convulsions resembling epilepsy are not infrequent. These attacks can often be accompanied by or traced to an increase in the physical symptom of constipation, flatulence, and "indigestion." In the severest cases delirium, coma, illusions, or delusions may occur. The sensory, motor, and sympathetic systems are usually affected. Myalgias, neuralgias, and neuritides are very common and respond quickly to the proper treatment of the intestinal condition, resisting the usual coal-tar products. The motor symptoms are usually due to irritation to the central ganglia. Irritation of the sympathetic system is shown by vasomotor disturbances, as flushing of the face, tachy- or bradycardia, irritable stomach, dermatographia, polyuria, and interference with the ductless glands.

Joints.—Various forms of chronic arthritis are very common and possibly arthritis deformans. Joint pains and creaks with joint fremitus are very common.

Abdominal examination shows signs of intestinal stasis, crepitation over the colon, especially the cecum. Splashing, tenderness, and a "doughy" abdomen are very common. Signs of enteroptosis are contributing evidences of a tendency to this intestinal condition. They are positively to be looked upon as a frequent accompaniment of intestinal toxemia rather than as a direct cause. This point is of great importance in differential diagnosis as regards surgical intervention. Fecal masses in the colon can often be demonstrated and also collections in the rectum and sigmoid flexure.

Therapy of Chronic Intestinal Toxemia.—The treatment can be subdivided into that for (*a*) intestinal putrefaction and for (*b*) chronic intestinal toxemia proper.

The treatment of intestinal putrefaction consists of a primary purge, preferably castor oil, which should be given for two or three doses, one ounce every other day. The dietary is based upon the withdrawal of all meat protein or an admixture of carbohydrates and fats without complete protein withdrawal. This latter diet is given with the idea that if a sufficient quantity and quality of these substances be given they will withstand destruction and bacterial processes in the upper intestine (E. E. Smith[3]). The employment of this dietary may be very successful, but its efficacy may be shown by the use of glucose and starch enemata. The author believes in no compromise, however, and gives no meat protein for several days. Colon cleansing irrigations of saline solution are very useful here and should be given until all evidence of putrefaction are absent. Catharsis, fasting, and colon irrigations will usually clear up intestinal putrefaction. Fermented milk with lactic acid bacilli, buttermilk, or even sweet milk and cereals and simple stewed fruits alone should be given. Drugs at this stage are harmful. As putrefaction may occur at any stage of intestinal toxemia and often recurs, the treatment may have to be repeated.

Diet.—The diet in chronic intestinal toxemia proper is all important. (*a*) On account of the close association with and danger of intestinal putrefaction, it is necessary to withdraw all meat protein except that contained in milk, cream, and butter. This includes all eggs, meat, fish, shellfish, and meat extracts. After a reasonable time, say three months, an egg and a little bacon is allowed and the patient watched for symptoms. Meat can then be added gradually if the grade of toxemia is a mild one. Relapses should always be treated by a complete withdrawal of meat.

(*b*) Prohibit all white refined flour and substitute whole wheat. The white flour of to-day is so highly refined that the nutritious substance (so-called "vitamines") and salts so necessary for proper metabolism have been removed. Prolonged eating of this white flour has shown bad results in intestinal toxemia, and it constipates. Polished rice should be placed in the same class and forbidden, non-polished and uncoated rice being substituted. If starch digestion is poor, it is unnecessary to eat large quantities of these two articles.

There are numerous difficulties in this dietary of whole wheat products to be overcome. I usually divide the patients into two classes: those who eat at home and those who eat in restaurants. Those in the former class have a much better chance than those who roam around for their meals. We often cannot spend much time on this class unless they will eat in certain specified restaurants where the dietary is cared for. Whole wheat flour does not keep well and is subject to parasites. It is not always easy to obtain. One reason of this is that it is not popular, as the public have not been educated as to its worth and it is not considered as palatable as the white flour. This can be overcome by the education of our cooks who can be taught to make delicious cakes, waffles, griddle cakes, biscuit, gravies, sauces, etc., with the whole wheat flour with but a small addition of white flour if necessary. If we should watch our cooks we would be amazed at the large quantities of white flour used in the preparation of our food.

Oatmeal and whole wheat cereals should be used freely; among the latter the old-fashioned cracked wheat is being revived and is an excellent substitute and a welcome change for the tired palate. The various proprietary and ready-prepared cereals are generally speaking poor foods, especially as all food should be thoroughly cooked.

The modern corn products are also pernicious. Wood[4] says that they are low in nutritious substances, especially fats and phosphorus pentoxide, which is a reliable indicator of the so-called vitamine so essential to nutrition. In the place of these we should use the old-fashioned corn meal containing the sperm. Wood says that foods containing large amounts of finely milled flour should be classed as furnishing a "deficiency diet."

(*c*) Vegetables. Green vegetables are very important in the dietary. One factor in the improvement of our patients during the summer months, I believe, is the abundance of this class of food stuffs. Fresh vegetables are to be preferred to the canned, but cannot always be obtained throughout the winter months except in the large cities where the small venders are of great value. I have tried in vain to get fresh vegetables in country towns during the winter and have had to ship them from the city. It is possible to obtain them if we take the trouble. Dried vegetables are excellent. The large hotels, however, feed their guests largely on canned goods for reasons best known to themselves.

I have had as patients head waiters in some of our best known hotels who inform me that they cannot obtain in the hotel restaurant the simple diet recommended. In certain instances the manager of the hotel has taken the trouble to place the diet within reach. The real reason of this condition is, of course, the lack of public interest and insufficient demand for the "simple life." In the choice of fruit and vegetables, we must be guided by our idea of the condition of metabolism in the patient. A chemical blood analysis is necessary or at least of great help in determining the amount of sugar excess or retention. In cases of flatulent dyspepsia due to carbohydrate intolerance or where the blood sugar is above the normal limit, it may be necessary to restrict the vegetables to the class commonly designated as the 10 per cent. and 5 per cent. (carbohydrate) vegetables or in diabetics to the 5 per cent. vegetables alone. These are special cases where the diet has to be very carefully arranged.

Ordinarily the list of vegetables, all well cooked, includes string beans, young lima beans, spinach, asparagus, brussels sprouts, beet-tops, kale, rhubarb, celery and celery knobs, carrots, beets, squash, mushrooms, parsnips, turnips, vegetable marrow, artichokes, cauliflower, and potatoes, white or sweet. Vegetable salads are useful to vary the monotony. They should be made with well cooked vegetables and lettuce, endive, etc., and dressed with olive oil and lemon juice in the place of vinegar, which may be a gastrointestinal irritant. Macaroni, spaghetti, and noodles, unless made from the whole wheat flour, are not permitted. In severe grades of intestinal toxemia the vegetable fats and oils should be substituted for the animal products as butter and cream, and are indicated when fats are needed for metabolism or for constipation.

(*d*) Fruit. Cooked fruit should be eaten at least twice and usually three times a day. Unless there is carbohydrate intolerance, the best fruits are apples, prunes, pears, and peaches, preferably fresh, but may be dried. Raisins, cherries, apricots, cranberries, huckleberries, blackberries, strawberries, raspberries, bananas—all cooked and preferably fresh—have their usefulness unless some idiosyncrasy exists. Of the uncooked fruit allowed are oranges, lemons, grapefruit, melons, unless some special reason exists for their being withheld. In glycosuric conditions, we must limit the fruit to the 5 per cent. or 10 per cent. (carbohydrate) fruit as indicated.

(*e*) Nuts are a welcome addition to the diet and are usually well tolerated unless gastric digestion is very poor or some idiosyncrasy exists. They are walnuts, hickory nuts, pecans, Brazil nuts, peanuts, beech nuts, pine nuts, and almonds. These may be made up into bread, cakes, or desserts. They may be home ground in inexpensive mills which also grind wheat and corn. The 10 per cent. or 5 per cent. nuts should be carefully followed in glycosuric conditions.

(*f*) Milk Products. Milk is one of the most useful and often indispensable articles of diet. Sometimes it is contraindicated as when an idiosyncrasy exists or when it is constipating. Bacterial content has much to do with tolerance. Buttermilk or fermented milks will often counteract these effects. Sour milk or sour milk cheeses are very useful. The good effect of milk is probably through its lactose content as shown by recent experiments of Hull and Rettger.[5] Rennet is a very digestible and useful product. The cream cheeses are not so efficacious and the hard cheeses, such as American, Roquefort, Camembert, Swiss, and Dutch cheese, etc., are contraindicated on account of tendency to constipate. Cream is usually well borne and in 20 per cent. strength can be taken up to one-half pint per day; it is of aid in constipation.

Sugar is necessary and will make up for some of the calories lost by the reconstructed diet. Brown sugar or molasses helps constipation. Tea and coffee are allowed in moderation provided no contraindications exist. Cocoa or cereal coffee may have to be substituted.

In choosing vegetable foods, it is interesting to consider those that have a high percentage of ash,

the most important of which are phosphorus pentoxide, calcium oxide, and iron. According to the statistics of Henry C. Sherman,[6] their order of value in percentage of edible portion is as follows: Rye and wheat bran, dried beans, cocoa, caraway seed, dried peas, almonds, peanuts, chocolate, oatmeal, rye flour, dried sweet corn, gooseberries, vanilla bean, and cottage cheese.

According to the percentage of 100 calories, the following articles lead: Celery, canned vegetable soup, spinach, mushrooms, lettuce, leeks, pumpkin, rhubarb, asparagus, dried beans, cowpeas, string beans turnips, parsnips, tomatoes, dried peas, fresh peas, cauliflower, and lima beans. The white potato is placed way down the scale chemically, but practical experience in Europe during the war has demonstrated that it is the most necessary of vegetable foods and cannot be wholly replaced by any other one vegetable. The potato should be baked or boiled in the skin, otherwise large amounts of the salts are lost in the water. This could be saved, however.

Among the foods, rich in carbohydrates, which should be avoided in marked flatulent dyspepsia, are in their order of carbohydrate content: corn starch, tapioca, hominy, rice, farina, oats, and prunes. Gelatin, being high in animal protein, should not be used. Alcohol in any form is not to he used, as it is a gastrointestinal irritant.

Agar agar is in great favor with the author. Its use and method of action by extracting water from the walls of the intestine and forming more liquid contents is well known. Its action is perfectly harmless and as a habit former is not bad. In some cases of colitis, however, it is irritating and causes pain and colic. It should be given in dram doses, mixed with the food three times daily; the dosage can be increased or diminished. It can be given in cracker or biscuit form and mixed with bran. It should not be medicated with laxative drugs.

Vaccine Treatment.—Autogenous colon vaccines are the most powerful agents that I know of in the treatment of chronic intestinal toxemia. Their rationale, preparation, and method of administration has been fully described by the author.[7]

It is advisable to make an autogenous colon vaccine from the stool of every patient with a long standing intestinal toxemia. The results of administration are sometimes amazing and their least effect is to cure or improve the patient in about half the time usually taken by other means, if the case is suitable. The interval of dosage has been arbitrarily set at four days for six to eight doses, and then weekly. The severity of the case and the result usually determine their continuance and dosage. The initial dose is from 25 to 50 million and the maximum dose 300 million.

In relapses, which often take place, a few doses of the vaccine with a rigid diet will give quick results. In some cases, the author has accomplished results with the vaccines alone without a special diet, but he is convinced that the best results are accomplished in conjunction with diet.

It is essential to consider the liability to recurrences of intestinal putrefaction and right sided colitis already referred to as the usual lesion found to accompany chronic intestinal toxemia. Catharsis and irrigations should be used only at the discretion of the physician.

Drugs.—Drugs have very little effect upon these conditions except to be detrimental. Intestinal disinfectants, as phenol salicylate, creosote with lime, magnesium salicylate, castor oil in minimum doses, are sometimes of use, but we should always question the diet first and rule out some anatomical condition, such as ptosis or kinks or growths, before even thinking of them. Mineral oil is probably used more than any other form of therapy. In my own experience, it is only a makeshift but very useful where a proper control of the patient, as in dispensaries, is possible. It may also be very useful when traveling, when some laxative is necessary and a proper diet unobtainable. Long continued ingestion of mineral oil will keep up intestinal toxemia because it does not cure the condition. The same objections or even stronger ones exist for olive oil which, however, if pure is excellent in small doses as a food and as a physiological chologogue.

Colon Massage and Vibration.—In competent hands, mechanotherapy is not only very valuable but often essential. The method depends upon the skill and training of the attendant. A good colon masseur is part of the office equipment. Real massage should take the place of all laxatives except as outlined by the diet. Electrical treatment of the abdominal muscles has given excellent results in the hands of many and is often indicated. It is not always easy to apply all this therapy to the busy man or woman, and often the financial means are limited. In many instances instruction will place the treatment in the hands of the patient so that with "medicine ball" abdominal exercises and the ordinary rules for constipation good results may be accomplished. These are, however, the simple cases in which the right colon is not seriously diseased.

Skillful vibration in the hands of the physician himself will often accomplish wonders and relieve in two to four weeks a constipation of over twenty years' duration. We notice the big drop in attendance in our intestinal clinic after a skilled colon masseur has left, for it is true that the poorer class of people generally know what is best for them and when they get results.

Enteroptosis.—Enteroptosis of moderate or severe grade should always be attended to. Posture is the keyword to this situation. Abdominal belts or preferably corsets are often essential. These must not only be mechanically efficient, but must also be applied under supervision of skilled attendants. The patients must be "followed up" and alterations made from time to time. A skilled corset maker and attendant are also part of the office equipment. Posture treatment should be carried on at night by the elevation of the bed. This can be done gradually, beginning with four inches in the very nervous and six in the others, raising by two inches every few nights until the limit of tolerance is reached, which is usually between twelve and eighteen inches.

The *psychological* side must not be lost sight of in therapeusis. One of the principal things that the patient needs is encouragement and suggestion that all will be well. It is often advisable to take the patient into your confidence and explain that relapses are the rule, but that they will be of short duration and less and less severe, and also that the improvement will be slow but progressive. If the doctor loses his patience and interest, the result in

the patient is obvious. The real reason that many of these poor creatures do not get well is difficulty in obtaining the right sort of a doctor, who will persevere and be sympathetic but firm. It is a case of endless detail which does, we must confess, become monotonous. The fault lies often, however, on the patient's side, so that we can frequently foresee failure if we are good character readers. It is our duty, however, to give a fair trial in every case.

Surgical Therapeusis.—In every case where obstructive conditions such as adhesions, kinks, bands, intussusception, tumors, etc., exist, this is indicated, It is the border line cases that give us the most trouble. How is a decision to be reached whether or not a certain case should be operated on? What should be done after the abdomen is opened? At one time a compromise operation called short-circuiting was very popular. The end results have been, in the writer's experience, almost universally bad. Lane advised removal of the colon for every case of constipation that resisted medical treatment. This operation even in the hands of the expert has a high mortality and cannot be generally recommended. Draper has called attention to the functional importance of the left colon, experimentally, and he and Lynch have proved its value clinically. They have also shown why short-circuiting fails.

The so-called partial resection, or developmental reconstruction, of the colon to the second or primitive position, as practised by Bloodgood, Lynch and Draper, Mayo, and others, is a favorite with the writer in selected cases where the cecum and ascending colon are roentgenologically dysmorphic or so diseased as to resist medical treatment outlined above. It is not always possible to foresee the extent or character of the operation before laparotomy, but a persistent large residue of the opaque meal in the cecum with a profound toxemia, with no response to medical measures within a reasonable length of time, positively justifies operation. An operator experienced in this particular line is an absolute essential to success.

When the physical conditions are extremely bad and it is necessary to relieve the toxemia, ileostomy as rediscovered and popularized by Lynch (see Draper[8]) is very popular with the writer. This can be performed under local anesthesia and later a more radical operation done if advisable. The curative effect of simple ileostomy upon what Lynch[9] has called the segmental colitis of toxemia is often amazing. Appendicostomy and cecostomy give excellent results in special cases and can also be done with very little shock. The writer has seen several profoundly toxic and insane patients restored to normal mental equilibrium in this manner.

Plication of the enlarged bowel has given good temporary results, but has more often failed. It does not remove the cecocolonic focus of infection. Suspension of the colon and stomach in advanced and intractable ptosis is sometimes temporarily successful, but the author considers the basis for such operations as essentially faulty, physiologically, as is the short-circuiting technique. After all these operations it is necessary to consider that these are essentially medical cases and must be carefully followed up by medical treatment. In the author's practice medical and surgical therapeutics go hand in hand without any of the old discord and damaging jealousies. The author has seen a large number of operative cases, at first apparent failures, recover through energetic medical treatment.

Conclusions.—1. Chronic intestinal toxemia is a proper and useful term by which to describe a symptom complex which has its primary pathological seat in the cecocolon.

2. Position of the alimentary canal is etiologically important. The carnivorous types of man are predisposed to toxemia. This may be due to other characteristics than mere morphology—which is an outward manifestation of unknown reactions to modern diet and conditions of life.

3. Since most symptoms are protective, constipation probably is. It is not the cause but an accompaniment of intestinal toxemia.

4. No case should be touched surgically until medical treatment, especially by colonic vaccines, has failed. In such cases it is probable that the cecocolon is extensively diseased and that no operation short of developmental reconstruction will be of permanent use.

THE DIAGNOSIS OF PULMONARY TUBERCULOSIS IN CHILDREN OF SCHOOL AGE.

By MAURICE FISHBERG, M.D.,

NEW YORK.

Clinicians are apt to forget the fact established by pathologists that tuberculous infection produces different effects in infants and children than in adults. During the first year of life, if infection is followed by disease—and it is in the vast majority of cases—the malady is acute and progressive, not unlike that observed in rabbits and guinea-pigs after inoculation experiments. In children of school age the vast majority of tuberculous infections are not followed by evident clinical symptoms, as is clear when we recall the large number of children who react to tuberculin, yet are hale and healthy. In the comparatively few cases in which the infection is followed by disease, the lungs are only rarely the site of the lesion. Acute or subacute tuberculous disease of the bones, joints, serous membranes, and, above all, the glands is produced. In fact, in whatever way the virus enters the child's body, the regional lymphatic glands react at once and may produce more or less serious symptoms. It is a noteworthy fact that pulmonary tuberculosis is

exceedingly uncommon in children affected with tuberculous disease of the bones, joints, or glands, excepting as a terminal phenomenon, or after surgical operation on the affected bones, joints, or glands, and then it is usually in the form of acute tuberculous bronchopneumonia.

On very rare occasions we do meet with chronic pulmonary tuberculosis in children of the same type and clinical forms as those observed in adults. When it does occur the symptomatology and physical signs are not unlike those seen in adults, and all criteria for diagnosis in adults hold for children. In fact, because of the thinness of the chest walls and the elasticity of the ribs, auscultation and percussion are apt to give better results which may be more properly interpreted than in adults in whom the thick muscles and excessive adipose tissue, as well as ossification of the costal cartilages, are often disturbing factors in physical diagnosis.

As was just stated, tuberculosis of the lungs is rare in children and the vast majority of cases in which it does occur we find the cardinal symptoms and signs of phthisis in adults to some degree. Because no distinction is made between tuberculosis of the lungs and tuberculosis of the intrathoracic glands, a great deal of confusion has arisen,, and it has been stated that special skill and care is needed to diagnosticate the disease in children of school age.

Children with pulmonary tuberculosis, if the disease is active, cough, have fever, nightsweats, tachycardia, emaciation, etc.

The cough may be mild or severe; it may be paroxysmal, coming on in fits and at times ending in vomiting, just as is the case with the emetic cough in adults. It may disturb sleep and be a strong factor in deteriorating the general health of the little patient. In the early stages, when the tracheobronchial glands are implicated and swollen, there may be hoarseness and at times a croupy cough or one not unlike that of whooping cough. I have seen cases in which pertussis was diagnosed. The emaciation is usually progressive, but very often, especially in mild and sluggish cases, the loss in weight may not be at all evident; the child may hold its own. But when we bear in mind that healthy children constantly gain in weight, going hand-in-hand with the increase in their height, it is clear that a growing child whose weight remains at the same level for months despite an increase in stature, is decidedly losing.

The fever of phthisical children may be of any type. In those afflicted with progressive disease it may be continuous, reaching 102° to 104° F. in the afternoon and stay at that level, or one degree less, during the morning hours. It may be remittent or, in the later stages, intermittent, accompanied by chills or profuse sweats. In most cases during the incipient stage the fever is mild, reaching 101° or 102° F. in the afternoon and dropping to normal or, more commonly, to subnormal during the early morning hours. This fever can be detected in some cases only when the temperature is taken systematically three or four times a day, per rectum, for one or more weeks.

It must be emphasized that fever in children is not of that same diagnostic significance as in adults. In children instability of the temperature is very common and it does not take much to raise it. The least excitement or excessive exercise may elevate it. Slight gastric disturbances may act in the same manner. Many children with acute or chronic rhinopharyngeal catarrh, enlarged tonsils or adenoids have fever for months, while at times it is very difficult or impossibe to discover the cause for the frequent increase in the temperature, and it would be manifestly wrong to attribute all febrile manifestations in children to tuberculosis. In fact, a mild subfebrile temperature in children is not incompatible with excellent health. It is only in connection with other symptoms and signs of tuberculosis that a subfebrile temperature spells tuberculous disease.

In respect to nightsweats it must be emphasized that many healthy children sweat at night to the great dismay of their parents, some of whom have heard that this is a sure sign of tuberculosis. A point which has not been appreciated to the extent it deserves is that nightsweats due to phthisis occur during the early morning hours after the child has slept for four to six hours. But these sweats are very often overlooked by mothers who are asleep during these hours. But the sweats in non-tuberculous children usually occur, if at all, soon after the child is put to bed and these sweats are almost always noted by mothers who become alarmed, especially if the child happens to cough for any reason. Inquiry should therefore always be made as to the exact time the nightsweats occur, and if they occur early in the evening, they may be disregarded, unless there are other valid reasons for assigning them diagnostic significance.

The rate of the pulse is an important diagnostic criterion in these cases. Active tuberculosis of the lungs may be excluded when a child under ten years of age has a pulse rate of less than 80 per minute. Tachycardia is an almost invariable rule in phthisis in children; even more so than in adults. In progressive cases with high fever, the rate may be over 120; in far advanced cases the same holds true. In the early stages of sluggishly progressing or quiescent disease of the lung, it is hardly ever below 100 per minute in children under seven years of age and above 90 in older children.

But these symptoms may be present singly or in combination, in children with perfect lungs but suffering from focal infection of the hyperthrophied glands of the throat and nasopharynx, especially the tonsils and adenoids. Emaciation in children due to malnutrition from any cause is often accompanied by fever which may go on for weeks or months. Cough is a frequent symptom of nasopharyngeal catarrh due to any cause.

Enlarged glands on the neck should not be taken as confirmatory of the tuberculous character of the ailment. These glands enlarge in children having adenoids, carious teeth, pediculosis, etc. Indeed, over 50 per cent. of children of the poorer classes have more or less enlarged cervical glands, and tuberculosis is not the cause of the glandular hypertrophy in the vast majority.

Enlargement of the supraclavicular glands, on the other hand, is of greater diagnostic significance. It is in nearly all cases due to tuberculosis of the apex of the lung on the affected side, especially the pleura. To be sure, it is rare to find these glands

enlarged, but so is pulmonary tuberculosis rare in children.

With any or all the above symptoms found in a child of school age we should suspect pulmonary tuberculosis, but no diagnosis of the disease should be made unless the lesion in the lung is localized by physical exploration of the chest. A careful examination will reveal the local lesion in nearly all cases if there is one at all. The signs are practically the same as those found in adults, especially those in children over eight years of age. Nearly all the above symptoms may, however, be found in children suffering from tuberculous tracheobronchial adenopathy, but the prognosis in this form of the disease is much better than in disease of the lung. The physical signs of enlarged thoracic glands also are quite different from those of pulmonary tuberculosis. In pulmonary tuberculous disease the lesion is almost invariably localized in the apex, and the statements made by some authors to the effect that it is found at the base, or in the region of the hilus is due to a confusion of disease of the thoracic glands with pulmonary parenchymatous disease.

We usually find that the affected side lags behind in motion during respiration; in more advanced cases there may be seen some retraction, manifesting itself in deeper excavation of the supra- and infraclavicular spaces. Percussion yields an impaired note over the affected area, and when the disease is extensive it may be dull above the second or third rib anteriorly and over the supraspinous fossa posteriorly. Because the intrathoracic glands are, as a rule, implicated in the tuberculous process, the interscapular space on the affected side is dull. That light percussion is necessary to bring out these points is self evident; in children this is even more important than in adults. But it must never be lost sight of that dullness localized over the lower parts of the chest, even when unilateral, and when resonance over the apex is normal, is only rarely due to tuberculosis. Only when there is a pleural effusion, a thickened pleura, or in the terminal stages when the tuberculous process has extended all over the affected lung, may we find impairment of resonance over the base; but then we no more deal with an early lesion. Dullness over the lower part of the chest is frequently taken for an indication of tuberculosis when it is in fact due to a thick, adherent pleura following pleurisy, dry or with effusion. But if it is always borne in mind that pulmonary tuberculosis in children should not be diagnosed unless the lesion is found in the apex, many errors may be obviated. Bronchiectasis, which will be discussed later on, may also give an impaired or dull note over the lower part of one side of the chest, but here it will be found that the note over the apices is normally resonant.

Auscultation reveals tuberculous lesions in the chest of a child more clearly and reliably than in adults if the little patient is not fretful, but is willing to cooperate with the physician, which is not frequent with those under five years of age. Harsh breath sounds, or bronchial breathing, when localized over a circumscribed area in the upper part of one side of the chest, should be looked at with suspicion. It spells tuberculosis if at the same time there is also found impairment of resonance over the same area and there are functional symptoms. In most cases there will also be found some crepitant or fine subcrepitant rales, like the sounds emitted when something is fried on a pan. The same sounds when localized over the base of a lung should not be considered as of tuberculous origin without further proof. Bronchiectasis is very frequent in young children, more frequent than is generally appreciated, and in this disease we find impairment of resonance, bronchial breathing, or absence of all breath sounds, combined with subcrepitant rales over a circumscribed area in the lower part of one side of the chest, usually posteriorly. Following attacks of pleurisy or pneumonia, the same physical signs may be found for months, though the little patient appears, and is, in excellent health. But pneumonia and pleurisy in children do not predispose to tuberculosis. After recovery the child is no more liable to develop phthisis than the average child of its age. When "unresolved pneumonia" occurs, the pathological lesion is, as a rule, bronchiectasis.

I have seen several cases of multiple abscesses of the lung, verified by operation, which gave such local signs and which were considered tuberculous by some because of these findings on physical exploration of the chest. The fever in these cases ran a very peculiar course. For a week or two the temperature is around normal and the child feels quite well. But then, without any assignable cause, the temperature shoots up high to 104° or 105° F. or even higher, and remains at that level for two, three, or more days when it again declines, remaining at a normal level for a week or two. I have seen several such cases treated as tuberculous, sent to sanatoriums and kept there for months. The last case that came under my observation had stayed in a sanatorium for several months and was then transferred to a hospital for advanced consumptives, where the diagnosis was made, an operation performed, and the little patient recovered. The fact that in these cases a correct diagnosis may save the patient's life is important. A surgical operation will reveal multiple pulmonary abscesses, or pleural vomicae.

In many children suffering from adenoid vegetations of the nasopharynx there may be found some impairment of resonance over one of the apices, usually the right, and bronchial or bronchovesicular breath sounds; but only rarely crepitant rales. Inasmuch as they also cough, and may have fever and lose in weight, or not gain, which is the same as losing in children, the diagnosis of tuberculosis is apt to be made. But when we bear in mind that the fact that a child has adenoids is sufficient to account for the symptoms, and that children with adenoids are no more likely to be tuberculous than others, we may in most cases avoid such errors. Similar physical signs may be found in children with valvular heart disease, especially mitral stenosis. In fact, these children often expectorate dark blood clots. But when we bear in mind that tuberculosis is extremely rare in persons with heart disease, we may avoid such errors.

The *x*-rays are of immense value in the diagnosis of pulmonary tuberculosis in children if properly interpreted. The opacities seen at the hilus of most children may be an indication of enlarged glands,

and when the glands are calcified the shadows may be quite clear and distinct. But calcified glands in the chest are harmless, as a rule—the lesion has healed. In cases of pulmonary tuberculous lesions in children the opacities will be found in the parenchyma of the apex, just as in adults. But here again very incipient lesions may not at all reveal themselves on the plate, because infiltrations permit the rays to pass. Only caseated, sclerosed, or calcified tissue shows distinctly on the plate. And when opacities are found in apical fields they are always to be judged in connection with the constitutional symptoms. In other words, *x*-ray findings alone, without constitutional symptoms, do not justify a diagnosis of pulmonary tuberculosis; while constitutional symptoms, combined with positive findings on physical diagnosis, are sufficient to render the diagnosis conclusive.

We have left the question of tubercle bacilli in the sputum to the end because, as in adults, positive sputum should be the last which should convince us of the nature of a doubtful case. It is worthy of note that the statement made by many writers that children do not expectorate, and even when they do the sputum only rarely shows the presence of tubercle bacilli is based on the confusion of tracheobronchial adenopathy with pulmonary tuberculosis. In tuberculous glandular disease of the chest there is usually no sputum available; and if there is it is derived from the nasopharynx and is bacteriologically negative. It is of the so-called "closed" variety of tuberculosis. But when there is a pulmonary lesion the child coughs and expectorates sputum in which tubercle bacilli may be found in the vast majority of cases. In fact in nearly all the cases I have seen the sputum was positive when there was a pulmonary lesion. But, as was just stated, we must not wait for positive sputum in children as in adults. The diagnosis may be made by a careful analysis of the symptomatology and the signs elicited by physical exploration of the chest. By correlating the facts thus obtained, we may, in the vast majority of cases, arrive at a correct diagnosis. What we must bear in mind are the following points:

Pulmonary tuberculosis is exceedingly rare in children of school age.

In the comparatively few cases in which it is found, the physical signs and the symptomatology are practically the same as those found in adults.

The chronic and subacute nasopharyngeal affections in children, which are very prevalent, may be responsible for symptoms which are not unlike those of pulmonary tuberculosis.

Moderate elevation of temperature in children is very frequently due to focal infection of the nose and throat; it may occur without any assignable cause and is not incompatible with excellent health. Alone it is not to be considered pathognomonic of pulmonary tuberculosis.

Cough, expectoration, and even hemoptysis are more often caused by enlarged tonsils and adenoids, and also by organic heart disease than by pulmonary tuberculosis.

When a child fails to gain in weight it is not invariably an indication that tuberculosis is the cause; in fact, it is exceedingly rare that tuberculosis of the lung is the cause. Even if tuberculosis is responsibe, the lesion is, in the overwhelmingly large proportion of cases, in the glands, bones, or joints. When the tracheobronchial glands are affected, the disease is not at all dangerous; nearly all recover and it is extremely rare that it should suppurate and break through a bronchus, causing death by suffocation or bronchopneumonia. In rare cases some intercurrent disease may spread the tuberculous lesion and produce an acute pulmonary disease.

A lesion found by physical exploration of the lower parts of the chest is not likely to be tuberculous in character. Pulmonary tuberculosis should be diagnosed in a child showing signs of a lesion in a lower lobe of a lung only when tubercle bacilli are found in the sputum, or when all our resources have been exhausted in attempts at finding another cause for the disease.

Exposure to infection should not be overestimated in children of school age. Very few escape infection with tubercle bacilli before reaching the age of fourteen; the majority of those who have been infected do not suffer any visible inconvenience because of that infection. If disease is produced, the joints, bones, serous membranes, or, most frequently, the glands are the seat of the disease. These diseases are serious and are apt to be protracted, but the ultimate outlook is good, excepting when the meninges are affected, or when a surgical operation is performed in cases of bone, joint, or gland tuberculosis; such operations are frequently the cause of bronchopneumonia which results fatally.

The tuberculin test is of no diagnostic value in children over four years of age. It surely indicates infection, but what we want to know is whether the child is sick, and this information tuberculin does not supply.

57 East Ninety-third Street.

MILK BACTERIA WHICH PROLIFERATE BEFORE, AND THOSE WHICH SURVIVE PASTEURIZATION.

NEW METHODS APPLIED TO MEET AN AS YET UNREMOVED MENACE.

By J. M. W. KITCHEN, M.D., M.S.,

East Orange, N. J.

He who thinks that the public milk and butter supplies are good enough, or that it is an easy task to apply practically a successful plan for the solution of those problems is in error.

I find it necessary in intelligently reporting progress in this connection to explain my personal relation to the milk reform movement, even at the risk of appearing to be egotistical in taking a prominent position in that work. Although I have done some important work in this connection, I am learning something new almost every day in regard to this great many-phased subject. During the last five years I have discovered some facts that are of scientific value that I believe are as yet not known to most medical men and to sanitary experts. I am giving all the shortening balance of the time and energies of my life to this movement, and it is necessary for me to have help in many directions if I am going to secure any practical application of

various matters that I assume have been evolved by me. The great obstacle that I and all the rest of the world are up against in this matter is the vast ignorance which generally prevails. I confess that if I had known how dense that prevalent ignorance is, I would have been discouraged in taking up the burden of this particular work. As I am already advanced in years, and life is an uncertain matter at the best, I ask to be allowed to herewith place on record some special information that has come to me since my communication to the MEDICAL RECORD, published in the issue of May 16, 1914.

That the present milk supply is so far from being as satisfactory as it is supposed to be, was a fact that I did not realize prior to the time I took up this special work. I undertook the work because I thought it my duty to do so, inasmuch as I had been experimenting in dairy matters for thirty-five years at my New Hampshire dairy farm and summer residence, as a matter of pleasurable interest. During that time I made various discoveries of scientific interest that, in connection with a certain inventive capacity, have led me to originate what I claim is a completely successful plan for securing a public milk supply that will be substantially entirely safe and sufficiently wholesome, at a cost that the masses will feel willing to pay. It had become obvious that the clean-milk movement that was inaugurated by Dr. Henry L. Coit and fostered by the Medical Milk Commissions, although of considerable benefit, had not been entirely satisfactory because of the cost of such milk, because raw milk cannot be known to be assuredly safe, and because none of this milk is given even the partial protection of ordinary pasteurization.

In seeking to solve a problem of this kind, one must first of all know what is generally known, and then gain knowledge requiring much experimental investigation. The situation disclosed to me by such study indicated as follows:

First: That all milk is more or less infected, at the point of production, with various types of germs that collectively may for convenience be classified as putrefactive bacteria, the proliferation of some of which at least may occur at temperatures much lower than the temperature that will inhibit acid-forming fermentations. There is no reason to assume that the products of fermentations of the so-called putrefactive types are harmless. Some of these products are unquestionably seriously poisonous. The evidence in hand points to some of them as being the direct immediate cause of much infantile mortality.

Second: Small infections of these bacteria may, under favorable conditions, develop into vast hosts, excreting unwholesome or dangerous products, and small infections may be largely composed of objectionable types.

Third: Large primary infections may produce large amounts of objectionable ferment products in relatively short periods of incubation.

Fourth: Pasterization as usually practised does not destroy all of those so-called putrefactive types, and especially those that are most resistant, including a few spore bearers, and which are most likely to develop malign ferment products! There is no evidence in hand to show that objectionable ferment products are eliminated by the heat of ordinary pasteurization, nor does very high sterilizing heat destroy some bacterial poisons.

Fifth: Milk may at various times become infected from tuberculous cows that do not react to the tuberculin test, or that are not discovered by physical examinations. The impracticability of a general thorough testing of cattle is well known. Furthermore, there are occasionally, and sometimes frequently, accidental, unforeseen, and unpreventable infections from typhoid, dysenteric, and various other pathogenic forms, whose presence in so good a culture medium as milk, is, of course, a public menace. The milk commissions report the incidence of previously undetected reactors in a large number of certified herds.

Sixth: Bacterial infections work through the cardboard substance of, or past the sealing surfaces of the ordinary paper-pulp milk-bottle closures; and infections of the pouring surfaces of the container may infect the milk during its pouring. In the old style of bottle, practically every bottle lip becomes infected, either harmlessly or harmfully.

Seventh: Milk is almost always distributed to consumers under conditions in which the temperature of the milk is sufficiently high to allow of bacterial and spore proliferation in the milk. In fact, no milk consumed has hitherto been subjected to sufficiently extended intense temperature influences to prevent germinal growths in it, both before and after pasteurization. This being so, we may assume that even condensed forms of milk contain more or less putrefactive products of questionable character.

Eighth: Governmental investigations show that about 20 per cent. of milk, cream, and also butter, are infected with undestroyed tuberculous bacteria of the bovine type.

Ninth: I have discovered that some putrid products found in milk and butter, and which had been supposed to result from bacterial action in milk *after* the production of the milk, really originate from putrefactive action in the sebaceous glands of the cow's hide, and became diffused into the air inspired and thence into the milk from the fluids of the cow's body, at the time of the production of the milk.

Tenth: The presence of putrefactive volatile products in milk and butter are more or less masked by low temperatures, but are thrown off and disclosed by high temperatures.

Eleventh: Aeration during cooling of milk retards the elimination of volatile contaminations, while aerating during heating of the milk promotes their elimination.

Twelfth: Under the prevailing methods of testing and inspection, there has been no practical way devised to indicate just where individual points of danger may be. Hence, to overcome that menacing uncertainty, *all* the supply should be protectively treated.

Note here that about the same proportion of butter is virulently infected as of milk, though the danger from butter is not so great as from milk, inasmuch as germs do not proliferate in fat; and attending motile conditions are less favorable for germinal activity in solidified butter. Also note that butter germs are carried through the alimentary tract in a large measure embodied and retained in the butter. Also note that only minor parts of the

supply of milk, cream, and butter are even partially protected by pasteurization, and that about two-thirds of the pasteurized supply is only flash-protected; and only one-third by the holding method. So-called pasteurized butter is butter made from cream that has been only more or less thoroughly pasteurized, but is subsequently reinfected from "starters" by inoculation and fermentation, and is compounded with infected salt, butter-color, and wash-water. An entirely new method of making butter should be adopted to secure absolute safety and wholesomeness in that product.

In view of the fact that practically all methods of bacterial testing of market milk give little or no information as to the specific character of the infections, it is permissible to point out that there is not a single package of milk, cream, or butter sold to-day that can be known to be absolutely safe and entirely wholesome. Certainly, while that condition prevails, the character of market milk, cream, and butter is not as good as it should be.

With such a situation existing, is it any wonder that even the most earnest students of the question have hitherto failed to provide any entirely practical remedy for the situation?

Let me recite now what is scientifically known as to certain related facts:

Milk of all degrees of cleanliness is probably always more or less infected with bacteria that proliferate at temperatures lower than those which are at the present time generally applied in preserving milk, although the optimum temperatures for growth may be between 70° and 100° F. It is also definitely known now that a number of varieties survive the ordinary pasteurizing temperatures. The publications of the United States Department of Agriculture, through its Bureau of Animal Industry, indicate without question that so many types of bacteria survive the 140° or 150° F. of heat, with a 30-minute holding, and the most resistant of which are open to suspicion as being noxious, that it is reasonable to conclude that some advanced method of treating milk should be practiced other than what is now in general use. All pathogenic germs are supposedly destroyed by efficiently conducted ordinary pasteurization; but there are a number of bacteria that survive the heat of 170° F. maintained for 30 or more minutes, including some of the acid-forming types. It is thought that all of the streptococci succumb at 175° F. Some of the peptonizing and spore-forming types resist even a temperature of 200° F. maintained for longer than five hours.

All of which goes to show that the treatment of milk requires something in addition to a mere temporary pasteurizing heating. The bacteria which resist ordinary pasteurizing heat have been variously classified as acid-forming, acid-coagulating, liquifying, peptonizing, alkali-forming, gas-forming, and inert types. We, however, know so little about the individual character of a large number of the milk bacteria that, in considering the matter from a practical remedial point of view, I have thought it well simply to classify these bacteria into two types, namely: the pathogenic, and the putrefactive, which produce putrefactive smells and tastes even after a 200° F. of heating and long holding; the latter comprising the non-pathogenic types, including those that are destroyed by ordinary pasteurization, as well as those which survive that heating. Ordinarily the heat of pasteurization, which is usually about 140° F., destroys 95 per cent of the bacteria, while at 150° F. 99 per cent may succumb. But it is obvious that even in the 1 per cent that survive there may, under favorable proliferative conditions, be reproductive increases of innumerable bacteria. Some bacteria are much more resistant than others. The numerical incidence of the primary infection has little to do with the numbers that survive. Some very clean milks show a large residue percentage of undestroyed bacteria.

The largest proportion of the bacteria destroyed are those which succumb in a thirty minutes' holding, most of which are presumably harmless. Still, several hours of holding may greatly reduce that residue. Rapid cooling after pasteurization does not appear to have any result in reducing the bacterial content, but slow cooling after pasteurization largely increases the development of the undestroyed germs. Heating milk at various temperatures between 130° and 200° F. varies the proportion of the several types that survive. The peptonizing germs seem to be more resistant to heat than any of the others that are commonly present, and as some poisons are split proteins, such survivors are open to suspicion as being dangerous.

We have to admit that up to the present time we do not know which of the infecting germs are those which develop the most objectionable toxins; but inasmuch as we know that toxic principles are developed in milk, it is merely a matter of common sense to treat the entire supply in such manner that no proliferation of any undestroyed germs in the milk can occur to any objectionable extent. If milk is given a markedly acid fermentation, it is reasonable to assume that some of the formed acids will constitute part of the more objectionable ferment products. It has even been proposed to encourage a lactic acid fermentation before pasteurizing, in order to secure a deterrent effect against the possibly objectionable undestroyed germs that survive pasteurization; but inasmuch as there is no sufficient evidence to show that lactic acid destroys those germs, is it not better to prevent *all* fermentation at all times in milk?

After five years of special study of possible remedies, following some thirty years of experimental investigation, I believe that I have finally evolved a plan which, if applied, will be remedially successful. We may, of course, accede to the generally held idea of preventing infections so far as it is practically possible; but as a matter of fact, so far as the general milk supply is concerned, a considerably large infection is the usual condition and cannot practically be prevented.

The remedy is quite simple, but involves such changes in treating milk that new working capital must be invested in installing new equipment. At first it would seem that so simple a plan as that which has been evolved ought to have been perceived to be the obvious thing to do by every one. Yet it apparently has not been obvious or practised, and in fact it is not practised to-day. In working out this remedy, the first thing that seemed to be needed was the evolution of a final container that

would prevent infections of the milk in the container during and after pasteurization, and of the pouring surfaces of the container's lip; and, also, that would permit of a successful application of the pasteurization of the milk in the container, after the sealing of the container, and furthermore, that would meet the peculiar commercial requirements of milk distribution. This feature of the problem consumed three years to accomplish, even starting with the ground that had been gained in the valuable practice of the Nathan Straus Laboratories.

Inasmuch as infections always do occur more or less in milk during its production, and usually more than less, the next idea applied was to prevent *all* fermentations in milk from the time prior to the loss of the natural power in milk to inhibit germinal growths, up to the time of the delivery of the milk to the consumer. This was practically accomplished by continually applying the influences of either hot or cold temperatures so intense that substantially all germinal proliferative action is prevented in the milk. Strange as it seems, this has never been done before as a continued process. This procedure entirely prevents any fermentative destruction of any of the nutritive properties in milk, and prevents the formation of and accumulation in milk of putrefactive fermentation products. Note here that the temperatures secured from icing, while effective against the quick souring of milk, do not sufficiently preserve the milk from the formation of putrid contaminations; especially if the milk has a large primary infection, or if it has been held for a long time before consumption. Putrescent character in food is certainly not desirable, and all milk that has not been counteractively treated shows putrescent character after a certain time of holding. The next remedial idea evolved was to aerate the milk for a much longer time and with greater thoroughness than is usual, to eliminate volative contaminations, and to accomplish that performance in a non-infecting atmosphere, either so hot or so cold that no proliferative bacterial action can occur in the milk during its aeration. This performance is easily effected at the distributing or producing plants. Preferably, the hot method should be adopted, because the desired effect can be more quickly attained, and because the milk can then be coincidently given a pre-heating, though only to a non-scorching degree, before placing the milk in the final container for complete, quickly-effected pasteurization at a higher heat. Note here that aeration during cooling restrains quick, thorough elimination of volatile diffusive contaminants; and that by the pre-heating of the milk at, say, below 135° F., a considerable shortening of the time of higher heat application can be effected, and thus some scorched taste in the milk be prevented. It is the empyreumatic changes in the taste of pasteurized milk that is objected to by so many consumers. It is more than questionable whether that change in taste has any undesirable effect of a digestive character. Nevertheless, consumers object to it. The application of sufficiently intense temperature influence should always be applied to milk to destroy pathogenic infections, no matter whether intense heat or intense cold is utilized in preventing fermentations before or after pasteurization.

The best gustatory result can be secured by a mixed cold and hot treatment; but if that practice is adopted, a more cleanly, and hence more costly, production must be practised; inasmuch as the so-called putrefactive germs that survive will proliferate in the intestinal tract as freely, if not more so, than in the unconsumed milk itself, with resulting autointoxicative effects. If the mixed treatment is applied, the milk should be deeply chilled by mechanically effective refrigerations applied at the farm, during transportation and in the special compartment in which the bottled milk is finally heated after its pre-heating. Here, after its pasteurization, the milk is cooled nearly down to its freezing point. Fifty degrees F. is not cold enough to prevent a large amount of reproduction of various bacteria. Although bacteria are not destroyed by temperatures below 35° F., still, proliferative action is so slow at those low temperatures that any objectionable fermentative effect may be disregarded.

This mixed method of treatment has two objections: (1) the low temperatures do not destroy bacteria, and (2) the method increases the cost of the milk one-half a cent a quart beyond that of ordinary market milk. This cost, however, is much below the cost of "certified" milk; for all the special costs of equipment and management of "certified" establishments are not needed to secure decently clean milk. Even "certified" *raw* milk is not good enough. It should all be pasteurized in a final container that will prevent infections of the contained milk, and should be *deeply*, mechanically chilled both before and after pasteurization in order to secure entire safety and highest wholesomeness; and also it should be pasteurized by more effective applications of heat than is usually given in ordinary pasteurizing processes.

The latest idea that has come to me, and which I think will ultimately be universally applied, especially in connection with the general supply of market milk and in the treating of cream for butter production, is to heat the milk or cream, and coincidently aerate in one operation, at the farmer's plant before the milk has lost its self-preservative power against germinal reproduction, to such a high degree, and so to maintain that degree of heat during transportation and holding, that all germinal life in the milk that is likely to be damaging is destroyed, and spore developments are prevented. Virtually the milk thus treated is in a high state of heat from the time of its production up to the time of its delivery to the consumer. In this method even the animal heat is economically conserved. Now this does not mean boiling milk. Some new procedure must be carried out to get the effect. In order to secure this effect without the scorching results of a sterilizing heat, I apply the principle of using large volumes of heat of moderate degrees of intensity for longer periods of time, instead of using heat of high intensity in lesser volumes for shorter periods, which later practice must be applied if a large amount of milk from numerous sources of supply is to be heated in the short time that is available for handling the milk by purveyors of city distributing plants.

If my method of heating is applied at many individual farmers' plants, the requirement of great celerity in heating is avoided; the formation of all putrefactive fermentative products in the milk is

prevented, and for practical purposes the cause of their formation is eliminated. It does this without changing the taste or chemical character of the milk more than the ordinary methods of pasteurization, but will eliminate most of, though not all of, the putrefactive and acid-forming germs. There can be no more objection raised against boiling milk for individuals of vigorous digestive ability than in soft boiling of eggs for consumption by such individuals; and if that objection does not exist, even less objection would stand against the now referred to new method of heating milk at a higher degree of heat applied in larger volumes than that of ordinary pasteurization, and holding the milk at that heat for a long time; even allowing that such heating may destroy the natural ferments in the milk, a possibility as to which, as yet, there has been no definite, generally accepted conclusion.

So long as prejudice exists against heating milk for the feeding of some infants, it may be well to adhere to the principle of applying, along with all possible cleanliness in production, the elimination of all volatile contaminations, heating to eliminate all pathogenic danger, and deep refrigeration against bacterial putrefactive reproductions before and after pasteurization. There should be no cessation from or restriction of that ideal for delicate babies, no matter what the cost. But such complicated precautions are absolutely unnecessary in connection with the milk supply of the vast major part of consumers.

We know that some bacterial poisons will resist very high degrees of heat without losing their toxic character. This being so, the importance of providing against their possible formation in milk by applying the herein stated ideas will be obvious, and will solve the great milk question. Practical action can be applied in this connection, but the whole world is as yet largely uninformed as to the matter. The adoption of the new methods requires that new capital be invested in installing new equipment and in educating the consuming public. At present, dealers are entrenched behind the ignorance of consumers, and health officials have no money in hand to educate consumers. I do not believe that any initiatory action can be secured unless some altruistic effort backs up already going concerns, as occurred in the "certified" movement, or organizes new purveying concerns. Although it is probable that such investment of capital would bring satisfactory returns; at the start, ignorant inertia and commercial selfishness must be overcome. Then the example will be followed by those who are less progressive and more selfish. Health officials, as well as the medical profession, should act to encourage investment of the newly applied capital that is needed.

The method of heating and aerating milk and cream at the farmer's plant is also the solution of the related problems of infected butter and the utilization of skim milk as a human food. Properly proportioned admixture of skim-milk powder and corn meal is the commercial solution of the high cost of living for millions of human beings; but at the present time there is no sufficiently effective practice in which a connection can be made between the easily decomposed skim milk of the farm and the general food consumer. Consequently, skim milk is wastefully utilized in feeding the lower animals, at an economic return to the farmer of less than one-sixth of its nutritive value as human food, and as compared with the cost of lean beef to the consumer.

There is still the question left open as to which of the above referred to methods is best suited for special purposes. For adults, and children over three years of age, in a normal condition of health, there can be no question as to the economic, sanitary and hygienic advantages of the continuously maintained hot method of control in preserving milk. So long as prejudice exists in medical minds as to heated milk there ought to be some source of supply for infant feeding in which the mixed treatment is applied, although it invariably involves a higher cost of production and preservation. Very clean milk, if deeply refrigerated before the milk has lost its inhibitive power against germinal growths, and if that deep refrigeration is continuously maintained, is practically a fresh milk for many days, and ordinary degrees of pasteurizing heat do not destroy the digestive zymogens. That method is theoretically the ideal, but in view of the vast amount of illuminative antebellum reports from Europe as to successful results from feeding infants with milk that had been subjected to the high heat of boiling, one feels justified in predicting that the clumsy, uneconomical method of preserving milk by ice refrigeration will at some time in the future be entirely replaced by a continuous method of applying heat in large volumes of low degrees of intensity.

It is nonsense to advance the proposition that a pasteurized milk cannot be considered as a "certified" milk. Depending on cleanliness of production alone was in harmony with the scientific enlightenment of twenty-five years ago; but it is *not* in harmony with the knowledge that we now have to help our practice. Certification of milk should include besides knowledge that it has been produced in the most cleanly manner, knowledge that it has been treated in such a way that accidental and unforeseen pathogenic infections have been prevented or overcome, and that *all* fermentative action in it has been entirely prevented, as well as volatile diffused matters eliminated that have become absorbed by and held in the milk.

The method herein referred to for securing a more effective application of heat, both in effectuating a greater destruction of bacteria and in preventing all fermentations and spore developments, has as a basic principle the application of the needed heat through a longer contact with heating surfaces that have been heated by steam that has been expanded under atmospheric pressure only, *i.e.* of water vapor of a temperature less than 212° F., instead of having been in contact with heating surfaces higher in temperature, such as is common in connection with the application of steam under higher than atmospheric pressure, and which surfaces are usually so hot as to scorch quickly the parts of the milk that have immediate contact with such highly heated surfaces. This scorched part becomes admixed with the bulk of the milk that is in the aggregate only heated to 150° F. or less. In my plan, by having the milk heated at the producer's plant immediately after its drawing, and

coincidently aerating the milk during its heating, a better pasteurizing effect is secured, fermentation is not initiated, and a more complete elimination of "cowy" volatile contaminants is gained. By shipping the milk in jacketed cans, in a highly heated state, we provide against loss of heat, a further reduction of bacterial life is reached, and probably a softening and increased digestibility of the milk is secured, as is the case in the use of the "fireless cooker." By giving the milk a relay heating at the distributor's plant after its bottling, and at a temperature of about 200° F., subsequent fermentation and spore development are prevented during its distribution to the consumer. Through this simple process, *absolutely* safe and *wholesome* milk can be secured for the masses at a cost to consumers very much below the cost of certified raw milk; in fact, as low or lower than grade A refrigerated milk, and of a gustatory character fully as good as that of milk that has been subjected to the change effect of ordinary pasteurization. This method enables unusual increases in bacterial counts, as from mastitis, to be followed to the individual herd at fault.

THE AUTOSERUM TREATMENT FOR CHOREA.*

By RUDOLPH DURYEA MOFFETT, M.D.,

NEW YORK.

ASSISTANT VISITING PHYSICIAN TO THE A. JACOBI DEPARTMENT FOR CHILDREN, GERMAN HOSPITAL, NEW YORK CITY.

In bringing before you this evening the subject of chorea and its treatment, I wish to give a brief description of this condition from an historical and from an etiological standpoint, and then speak of a new form of treatment which we have found so beneficial at the German Hospital in New York. Chorea was the name originally given to the cases of dancing mania which occurred along the Rhine, at the beginning of the fifteenth century. These cases of real chorea were followed by cases of pseudo-chorea which were in children or persons who imitated the real chorea. This became so extensive as to warrant being called an epidemic. Such epidemics have also occurred in Italy and France. In our own country, in 1803, such an epidemic occurred in Tennessee, and was well described by Douglas Robinson in 1825. Real chorea must be differentiated from the ordinary types of habit spasm such as twitching of one eye which is so common in children.

Chorea is a nervous disease which is usually characterized by involuntary movements of various muscles of the face, hands, and arms. It is accompanied by great muscular weakness and prostration. Not infrequently it follows attacks of rheumatism and tonsillitis, and is usually accompanied by endocarditis. A true chorea usually called chorea minor, was first described by Sydenham in 1686 and his description is so classical that it cannot be improved upon to this day. The literature is so extensive on this subject that it is hardly necessary in a paper of this character to go into it any deeper.

It is most common among females. We have found in our investigations of this subject that the proportion is 3 to 1, and it is most common between the 5th and 11th years, usually coming on at the end of the first half of the school year. We rarely see this condition during the summer months, so that worry, exposure to cold, dampness, and infections of the nose and throat and of the respiratory organs, seem to be forerunners of this condition.

We have almost reached a point, with our newer ideas on this subject, where we feel that chorea is an infection of the nervous system, the infection being similar to that which is caused by so-called rheumatic joints, the exact organism of which we have been unable to isolate. The disease acts like an infection and responds like an infection. By infection I do not mean that pus is present and that the patient runs a usual infection temperature, although most of our patients with chorea have a slight temperature. This belief is held to by numerous workers in the same field. Numerous examinations of the spinal fluid of cases of chorea by the newer laboratory methods of Rosenow have failed to show the exact cause present. As far back as 1850 Germain Sée stated that chorea was due to a rheumatic affection of the brain and spinal cord. This same belief has been shared by Osler, Townsend, Berkely, Koplik, and Goodman. That the poison is a microbe is suggested by the frequent unilateral character of the disease. It is almost invariably more marked on one side than the other. This, according to Cautley, indicates a local cerebral lesion rather than a general cerebral toxemia. It is probable that more than one organism can give rise to chorea, for attacks follow many infectious diseases.

Probably functional instability of the nervous centers is a potent cause and may depend upon malnutrition. One case which came under our observation at the hospital was in a child six years old who had been practically starved for some weeks and entered the hospital with little more than skin and bones. Proper feeding without autoserum improved the child's condition markedly and aided in its rapid recovery. The disease is most commonly seen among the poor and poorly fed.

The morbid anatomy in cases dying of chorea is that of any case dying from extreme emaciation. Endocarditis has been noted in 105 out of 115 autopsies collected by Osler; Sturgis found organic heart disease in 75 out of 80 fatal cases. Usually the mitral valve is affected but sometimes the other valves may be involved. The muscle of the heart usually has undergone fatty degeneration and not infrequently a small amount of inflammatory exudation may be seen between the muscle fibers. Reichardt in 1902 found changes in the nervous system which he believed were due to a general toxemia such as degeneration of the anterior and posterior root fibers in the cord and small-celled infiltration throughout the brain; also, small hemorrhages in the neighborhood of the basil ganglia. Neuwerck has noticed these hemorrhages also. No observer has ever been able to demonstrate any abnormality in the cortex of the brain.

It may be of interest to hear something about the chemical examination of the spinal fluids of children with chorea. Leopold and Bernhard[2] made 21 careful chemical examinations of the spinal fluid of children with chorea and the figures obtained

*Read at meeting of the Flatbush Medical Society, March, 1917.

for nonprotein nitrogenous constituents and for reducing substances showed no variation from the normal. The number of cells counted was normal except in 4 cases and the globulin reaction was negative in every case. No child with chorea has given a positive Wassermann reaction, which, in a series of 21 cases, would indicate that syphilis plays no role in this disease.

I will not take up your time with too many of the symptoms of chorea; they are probably all too well known to most of you; on account of their frequency and the long duration of the disease these cases usually pass through several hands before they are well. The onset usually takes from one to six weeks, the child seems more nervous, laughs and cries for little or no cause and is unable to fix its attention. Irritability of temper, awkwardness, and sleeplessness are common symptoms. As the condition progresses the muscles used in expression and in movements requiring the most careful coordination, suffer first and most extensively The child makes faces, drops things, is unable to pick up even a pin without going through many twists of its hands. Eventually the child is unable to stand, walk, or sit and flings itself about the bed so that it may have to be restrained. In many of our cases the children are in a constant perspiration, due to very active muscular exercise, as an athlete after running. The mental condition becomes much impaired and the children seem stupid or unusually dull. They are slow in answering or understanding questions. The motor disturbances show involuntary movements of practically all the muscles of the body, the tongue is protruded with a jerk and held out very often by closing of teeth. Speech defects are common and they sometimes lose absolute control of articulation. With speech defects there are voice defects which are due to movements of the muscles of the larynx. These speech defects are similar to the movements of the body, the voice rises and falls in rapid alternation. The reflexes are sometimes normal but very often diminished or absent. As I have said above, the general health becomes much inpaired and the blood picture is that of a child in secondary anemia. The heart becomes rapid and there is usually a loud systolic murmur at the apex, which can be heard posteriorily.

The prognosis in cases of chorea is usually good. Mortality has been placed at 2 or 3 per cent. This includes the adults. I have never seen a death in a child from chorea. I have seen one adult with this condition who died at the Brooklyn Hospital.

This is enough of a general description of the disease and I will now call your attention to a new form of treatment which we have used at the German Hospital, New York City, for the past two years, with some very remarkable results.

About three years ago Dr. A. L. Goodman[1] of the German Hospital suggested the use of autoserum in the treatment of chorea. This treatment, known as the Goodman autoserum treatment, consists in the taking of the blood from the arm of a patient suffering from chorea, separating the serum from the blood, and then injecting the serum into the spinal canal of the same child after withdrawing 15 to 20 c. c. of the spinal fluid. Since this treatment was first suggested there have been about 100 cases of chorea major treated in this way with very remarkable results in some of the cases.

At first the simple withdrawing of the spinal fluid was tried but no appreciable change in the movements of the arms, face, or legs was noted. This simple withdrawing of the fluid was later followed up by the injection of the serum of the child so affected.

Before going into the exact method of preparing the serum for use I would like to call your attention to a few precautions which we have found necessary before using the serum.

The patient should be kept in bed without medicine of any kind, such as choral, bromide, or arsenic, for four or five days before any treatment is instituted. In one case we injected a patient during the time it was under chloral and bromide medication which almost proved disastrous. The patient went into a coma which lasted for four or five days and we believed this was due to the fact that the child's nervous system was saturated with these drugs.

Another important precaution is to ascertain if the child has tuberculosis or syphilis, as these cases do not do well if injected. Children with enlarged thyroid do not do well if injected with autoserum—but improve when treated with extract of the thyroid gland.

Method of Treatment: Fifty c.c. of blood is withdrawn from one of the veins in the arm and then rapidly centrifugalized, which separates the serum from the blood. The serum is then pipetted into a sterilized vessel and placed in the incubator and kept at the temperature of the body. A lumbar puncture is performed in the usual manner and 20 c. c. of the spinal fluid is allowed to flow out. In cases of chorea this is usually under a little pressure. After 20 c. c. of the spinal fluid have been withdrawn the blood serum at the body temperature is then slowly injected. This usually takes about 5 to 8 minutes and the patient is kept in a recumbent position in bed for at least one or two hours after injection, for if allowed to sit up immediately after injection heart collapse sometimes follows. If the serum injection is to be of any benefit in a case of chorea, improvement should be noted in two or three days, in the very bad cases the muscular twitching of the mouth and movements of the arms become lessened, and one part of the improvement which seems to me as very satisfactory is that the children take their feedings much better after their first injection. This first injection is followed in 5 or 6 days by a second one which is performed in the same manner.

There are one or two things which develop the day following injection which should be noted but at the same time are not serious symptoms: A slight rise in temperature, vomiting, an increase in the pulse rate, and in some cases a slight stiffness of the neck. These all disappear within a few hours. Some of the patients have had a slight amount of frontal headache. However, these symptoms do not all appear in every case. It probably is due to a slight increase in the intracranial pressure.

Summary: It may be of interest to know that of the cases treated, five per cent. have had a recurrence within a year. This is considerably lower

than under the usual form of treatment. I believe that autoserum should be used in all cases of chorea minor, especially where they have resisted other forms of treatment. The usual routine treatment was formerly to keep the children in bed from 6 to 8 weeks, give them chloral, bromides, sodium salicylate, arsenic and warm baths, all with more or less uncertain improvement in the child's condition. With autoserum the course of the illness can be much shortened and the general improvement of the patient will be more rapid. I remember while working in the hospitals in Berlin and Strassburg that after 4, 5 or 6 weeks of arsenic, sodium salicylate, and bath treatment, the children were kept out in the sunlight and fresh air, without medication, for 6 to 10 weeks longer. With autoserum, if a child is to improve at all, it should be practically well within 3 weeks.

We have been unable to explain definitely why this method of treatment has been so satisfactory, but it is based on the supposition that we are dealing with an infection of the nervous system and that the child has developed in its blood certain substances or anti-bodies which have the ability to overcome the infection in the nervous system, whatever that may be. As yet, there have been only a few reports from other hospitals. Here in New York at the Fordham Hospital and the Jewish Hospital (Brooklyn) there have been a few cases injected with very satisfactory results, I believe. Faber has reported in the *California State Medical Journal* his observations on five or six cases and he also has found satisfactory results.

SOME DISFIGURING AFFECTIONS OF THE EYELIDS.

By DOUGLASS W. MONTGOMERY, M.D.,
San Francisco, Cal.

If the mouth may be considered the door of the face, the eyes are its windows, and the eyelids are the curtains. The eyes are the most expressive feature of the face, and the eyelids contribute more to the expression even than the eyeballs. Any deforming disease of the lids, therefore, makes itself quickly felt in the appearance of the face, even if the disfigurement itself cannot be precisely defined by the observer. It is because of this that any references to the eyelids in general literature are so interesting, as they are apt to show how these diseases strike the layman. Blepharitis marginalis is one of these deforming diseases.

Blepharitis Marginalis.—Blepharitis marginalis is an inflammatory condition of the free border of the eyelids, and is part of a general disorder of the skin called seborrhea. In seborrhea the skin becomes thick, dull, heavy looking, and often the surface is oily. In fact, the trouble primarily has to do with the fatty constituents of the skin, and as the skin is above all things a fatty organ, the importance of any interference with its fatty constituents or its fat production may be understood. The skin has great masses of fat beneath it, and its sebaceous and its sweat glands and its general surface produce an abundance of a fatty substance called cholesterol. Cholesterol is impervious to bacterial attack, it is non-fermentable. If, however, a fermentable fat instead of a non-fermentable fatty substance is excreted by the fat and sweat glands and by the general surface of the skin, bacteria will attack both it and the skin, and will give rise to many forms of catarrhal disease. This is just what happens in seborrhea. Seborrhea may cause an oily surface or it may give rise to a dry, branny surface—in the one case causing seborrhea oleosa and in the other pityriasis, a word derived from the Greek, *pityron*, bran, and therefore self-explanatory.

In any case of seborrhea the edges of the eyelids may be affected. The oily secretions of the very large sebaceous glands, the Meibomian glands, which lubricate the free edges of the lids and the lashes, may be altered, and they may secrete a hard brittle granular fat resembling barley sugar, which sticks to the lashes, and in the morning "gums up" the eyelids disagreeably. The patient may be constantly occupied in picking off these crusts. Instead of being tough and gummy the secretion may be free flowing and watery, and in either case the secretion is apt to give an opportunity for the residence of bacteria, which under ordinary circumstances would be harmless, but which in these people give rise to blepharitis marginalis and to inflammations in the Meibomian glands, commonly called styes.

Cervantes jokingly refers to how deforming these secretions from the eyelids may become. When Don Quixote demanded of the silk merchants that they should confess Dulcinea to be the most beautiful woman in the world, one of them waggishly requested Don Quixote to show them her picture, and then, with that small evidence, he said they would readily comply even if she were blind of one eye and that from the other there distilled vermilion and brimstone. Don Quixote disdainfully rejected the proposition and affirmed that nothing distilled from his lady-love's eyes but amber and civet.

It does not appear from this that Don Quixote mended the matter much as far as appearances went, but he satisfied himself.

Incidentally it may be remarked that sulphur had much to do with the physiology of the eye in olden times, as it was supposed to cause the glow occasionally seen through the pupil in man and frequently in the lower animals, as in the rabbit and cat, which we now know to be caused by the reflection of light from the retina. I have no doubt the reference to sulphur by the silk merchants was particularly insulting, as being intimately associated in ancient literature with vile odors and with hell. Civet, on the other hand, was appreciated as a perfume, and amber was highly regarded as shielding from disease.

Blepharitis marginalis may exist in young people, but it is an obligatory accompaniment of old age, that condition which has been compared to a hospital into which all diseases may enter. In old age seborrhea is naturally present both because

of the fatty degeneration of the tissues, including the epithelial tissues, and because of the anemia due to the failure of the blood making organs. The word anemia has come to mean not an entire lack of blood, as it logically should, but a lowering of the red coloring matter of the blood. This lowering of the red coloring matter causes a paucity of oxygen, which in turn leads to a faulty oxidation of the fat and the fat making starches and sugars. This interference with the digestion or burning of fat, starch, and sugar, has a decided effect on the great fatty organ, the skin. This relationship between anemia, old age, and seborrhea leads us to consider one of Hamlet's observations.

Hamlet was rather free in his criticism of his neighbors. He indicated, for instance, that amber and plumtree gum distilled from old Polonius' eyes, and he did not regard this as a compliment either, for he goes on to state that this distillation, together with weakness of the hams and a plentiful lack of wit, were the distinguishing characteristics of the old fellow.

This plumtree gum, or pituita, played as great a rôle in ancient medicine as did sulphur. The blood, the bile, the atrabile, or black bile, and the pituite or phlegm were the four humors of the body, which, when disordered, gave rise to disease. The pituite or phlegm was thought to come from the brain by way of the pore or dimple in the floor of the third ventricle, and on through the pituitary gland, and the solid, bony floor of the sella turcica to the pharynx. Some of it also went out through the optic nerves and eyes, and some through the cribriform plate of the ethmoid bones to the nose. The free and easy way a fluid had of passing through a solid structure, as even through the solid floor of the sella turcica, constituted one of the peculiarities of the old physiology. Previous to the discovery of the circulation, the blood was supposed to pass from the right to the left side of the heart through supposititious pores in the cardiac septum.

This pore in the floor of the fourth ventricle is now conjectured by Gaskell to be the last indication of that pharynx or passage between the primordial alimentary canal, represented by the central canal of the nervous system, and the new alimentary canal, our present one. What eons of ages this anatomical development represents, and what a short moment of time exists between Gaskell and Rabelais!

The phlegm, or pituite, was considered the most dangerous of all the humors, as disorders of it gave rise to the most serious and quickly fatal diseases.

Usually catarrhal inflammation of the lids is sluggish, partaking in this respect with the general character of seborrhea. The process, however, may be quite active, giving rise to marked redness, and this is particularly apt to occur in those who overindulge in alcohol. This is the reason why Bremond asserts that the "hospitaller" or lay brother hospital attendant, mentioned by Friar John as having eyes as red as an alder-wood bowl, was a drunkard.* As a child I well remember a carpenter who had eyelids every bit as red as the above mentioned hospitaller. He used to wear gold rings to keep the inflammation out of his eyes, but he nevertheless was well aware of the real cause of his trouble, as his favorite name for whiskey was "red eye." The easily fermentable fats, such as butter and cream, and the easily split corbohydrates, such as the sugars, are strongly sebiagogic. Alcohol, as being a modified carbohydrate, and being more readily absorbed and more easily split than sugar, is more highly sebiagogic in its action, as the shiny, greasy faces at a formal dinner often show.

There is a dirty yellow discoloration which occurs principally about the mouth and also on the eyelids, and which is associated with anemia and frequently with seborrhea. It sometimes is a decided lemon color, and is the same lemon yellow that occupies the entire complexion in Bright's disease. As I have encountered it, it occurs more frequently in women than in men, and is peculiar in that the person herself rarely observes it. Mothers frequently observe it in their daughters, and many a girl is sent repeatedly to wash her face, when in reality the digestive organs or the blood or both are at fault. It is rarely noticed by the patient as occurring on the eyelids, except as a generalization, as contributing to "a bad complexion." It may gradually deepen as years go by, till, at the age of forty or forty-five, the lids grow to be buff colored. The combination of a dull yellow, Swiss-cheese complexion with chamois leather lids is not unusual as part of the picture of a seborrhoic face.

As before remarked, one of the peculiarities about this discoloration, both about the mouth and about the eyes, is the infrequency of its being noticed by the patient. Many a woman who wears out the carpet in front of her looking glass has to have her attention especially drawn to it before she sees it. And when the physician finally does succeed in making the patient see the disfigurement, it does not follow that his services are further required.

The seborrhoic deformities are among the most common troubles of the human race, and their incidence answers the question so bluntly put by Guy de Maupassant, "Why are children so beautiful, and why do adults and those along in life become so ugly?" It is largely a matter of eating, or of anemia, or of a too sedentary mode of life. The question of eating resolves itself, as a rule, into overindulgence in the delicious, easily split, easily fermentable fats such as butter and cream, and the very attractive, easily split carbohydrates, such as the sugars, and their modification, ethyl alcohol.

No matter how earnestly one may advise one's patients, from my personal observation it will be a long time before eating for fun will cease to become fashionable. After spending my time and energy in exposing my reasons for a reasonable course of eating, I often conclude that John the Baptist was the wisest of all orators. After preaching some time in Jerusalem, he finally retired to the desert, where he presumably addressed the eyeless winds. The subsequent political events in Jerusalem, including the final catastrophe on Calvary, justified his course. If his subject had been dietetics I am persuaded the event would have been equally brilliant.

323 Geary Street.

OUTLINES OF NEW WORK CONCERNING THE ALCOHOLIC PROBLEM.*

BY T. D. CROTHERS, M. D.,

HARTFORD, CONN.

A RESEARCH Foundation has been established on the assumption that there is a great unknown continent of causes that have never been explored back of the use of alcohol as a beverage. This is sustained wherever inebriety and alcoholism has been studied with any degree of accuracy. Physicians who are treating the acute symptoms that call for help are astonished to find that when physical and psychical causes are recognized and means applied for their removal the most positive results follow. Thus, a surgeon who removes a spicule of bone that has evidently been pressing on the nerves, finds that the patient recovers from what is considered chronic alcoholism supposed to be incurable. Trephining the skull and lifting a depressed bone is followed by a total change in so-called habits and conduct. Finding pus pockets and removing them is also a surgical operation that is followed by the most unexpected results of cure. In the field of clinical study, correcting constipation and states of local congestion, also changing the diet, cutting off tobacco and a great variety of measures of this kind have restored many a poor inebriate. On the psychical side of inebriates, there are equally startling cures from psychical measures and means. These are the unmistakable hints of a new field or active, predisposing, physical and psychical causes which are not only associated with but have preceded the drink craze.

The present tremendous effort by reformers concentrated in prohibition is based on the theories of the past and assumes that moral causes and the vice element in human nature is sufficient to account for the great alcoholic evil. The commercial and sociological world are frightened at the extent and magnitude as well as destructiveness of alcohol as a beverage and they, too, have joined the wave of reform with most enthusiastic faith that the obliteration of the saloon and alcohol as a beverage will afford a complete relief from the present conditions.

When the disease theory was mentioned many years ago for the first time, it was most bitterly condemned. Later it was accepted in part and finally the quacks occupied the field with claims of specifics and positive cures from remedies and secretive means. This has somewhat passed away, but the thinking public realizes that there is a chain of physical causes that have never been studied. Scientific research everywhere brings out the fact that all the phenomena of disease are the direct result of a distinct range of causes that moves uniformly, controlled by exact laws which can be known. Thus the epidemics and mysterious diseases which have prevailed in the past are traceable and are found to be governed by exact laws of cause and effect.

The alcoholic problem, statictically, is this: There are over a million persons in this country using spirits and drugs either in moderation or excess. There are at least fifty or sixty thousand direct deaths from this cause yearly and many, many thousands who die indirectly from the same cause. Evidently, this army is recruiting all the time and is not diminishing. The religious, educational, social reform effort, while doing grand work, has not succeeded in diminishing the disease, mortality and frightful losses that come from this source. The obvious reason is that the causes are unknown and the measures of their prevention have not been applied along scientific lines.

This is the field the Research Work has entered upon. One of the most prominent phases is the periodic drinker. His use of spirits is mysterious and inexplicable. At one time he is a rigorous abstainer in possession of all his faculties, at another, he is an impulsive maniac—idiotic and unreasonable. The contrast between these two conditions is a subject of numerous theories, comments and opinions. This condition may change any time, or go on to death. The symptoms are so positive that it is assumed that a study would show some preceding causes which move with uniformity and could be predicted. A single instance seemed to furnish a distinct answer to this question and indicate a line of study of the most intense interest. Thus, in this case, a man of unusual intelligence and capacity drank to great excess at irregular intervals then recovered and resumed his business as before. These attacks were distinctly preceded by intestinal derangements and fears of cancer. This would extend to visits to specialists and most careful examinations with instructions of what to do, which he followed for a time, then suddenly drank to great excess. Here was a distinct delusion preceding his drink attack. It was found that before this broke out, he showed unusual attention to business, making elaborate plans to prevent losses. Another instance, equally prominent, suffered from an attack of so-called rheumatism with an equal alarm and anxiety to prevent it.

A very practical inquiry was made to determine if these attacks were preceded by symptoms, premonitory and significant of the approach of the drink paroxysm. Inquiry covering a number of persons under treatment showed that in every instance such symptoms were apparent although they varied largely in the individual. Inquiries made of thoughtful physicians who had patrons of this class brought out strong confirmations. The few medical papers written on this form of drink referred to this in particular, and one author indicated that in his opinion every case had premonitory symptoms although they were not always recognized. In a paper which I read on the Auras of Inebriety before the American Medical Association some years ago, this fact was brought out in some detail and the whole was based on the studies of several hundred persons. Recently this appearance of symptoms is so common as to be expected and when they do not appear the fault is evidently with the observer. These symptoms seem to group themselves into two classes, both physical and psychical. The former includes nearly all the so-called functional disorders and symptoms of prominent physical disease; the latter covers a wide range of mental symptoms, one of which is very misleading and by which the patient shows undue anxiety to help others of his class. He will become

*Read before the Society for the Study of Inebriety, at the annual meeting in New York City, June 12, 1917.

wildly enthusiastic in reform work and exhibit unusual buoyancy and startling dogmatism, then suddenly stop and become a victim himself. Observation shows that often the most enthusiastic temperance reformers whose efforts border on the intemperant acts and words very often relapse and become abject victims themselves. Every great revival illustrates this and often the most ardent converts to radical change of life are the first to break down.

Our studies covering a large number of instances were without exception distinct and positive in the premonitory symptoms and auras which preceded the drink craze. There was no accident or chance in this. It pointed to distinct unknown causes, irritations and morbid impulses that gathered and finally culminated in an intense overwhelming desire for the narcotism of alcohol. Of course these causes are largely unknown to the patient unless they are repeated in about the same way under similar conditions. Even then a recollection of them is faulty. A person of this class whose premonitory symptoms are of great irritation and suspicion before the drink attack breaks out may have an indistinct memory of this having occurred before. This memory does not carry with it any intimation of the almost certain sequelæ. He reasons that the causes of his present disturbance are different from that of any other time and when his friend intimates that he has acted that way before the idea that this preceded the drink attack is repellant.

There are others in which these distinct auras create alarm and dread of the approaching drink attack. A few of such persons make great efforts to stop this storm at the beginning. An instance of this kind is that of a man occupying a very responsible position, who becomes an insomniac several days before the drink craze breaks out. He has learned to put himself under the care of a physician, who gives him drastic cathartics and other remedies for a brief period; then the condition passes away and he sleeps well until the approach of another storm. These have been broken up so that the free interval is greatly lengthened and the symptoms minimized and overcome with a good prospect of their final obliteration.

There is a great wealth of illustrations along this particular line. The inference is very evident that all persons of this class could be greatly helped and many of them cured by a study of the early symptoms. The auras and changed conditions would go before the outbreak.

Our preliminary work fully sustains the following general conclusions:

First—There are definite physical and psychical states preparing the soil and sowing the seed for the outbreak and development of what is called inebriety and alcoholism. These are manifested by positive changes of character, conduct and mental activity. These are so tangible and real as to be observed by both professional and laymen, and be the subjects of comment and observation among the friends.

Second—Whatever the actual causes may be, either dating from heredity, toxemias or exhaustion, they give distinct intimations, often long in advance of the direction of their development and the form in which the outbreak will appear. Of course the memory of the pleasing effects of alcohol, either as a medicine or socially, gives form and shape to these impulses. Perhaps at first, experimentally to determine whether they will relieve present conditions and, aftr this fact is established, they dominate everything.

Third—Obviously there is an increasing army of highly sensitive active brain and muscle workers in this country. Sooner or later there comes the dominating impulse for relief and if alcohol has brought this in the past, it will be sought for in the future. The active results from continued strains and drains suggest relief from many sources, and these are the premonitory symptoms. The fever and chills in malaria indicate the presence of germs and toxemic conditions, and the dominant thought is what to do, in the same way. The premonitory symptoms going before alcoholism or inebriety are distress signals, actually danger signals which must be recognized in any method of treatment.

Fourth—This general study shows beyond question that not only periodic inebriates but so-called immoderate drinkers have distinct symptoms of disease, before the outbreak and the assumption is amply verifiable that a study of these symptoms would open a most fascinating field of prevention and cure. Studying the symptoms after the disease has appeared from the standpoint of moral theory must necessarily be disappointing.

142 Fairfield Avenue.

Medicolegal Notes.

Physician's Claim Under Workmen's Compensation Act.—In proceedings under the Indiana Workmen's Compensation Act for medical treatment of an employee of the defendant employer, who was injured in an accident, the Indiana Appellate Court holds that where an employer duly authorizes a physician's treatment of an injured employee beyond the thirty-day period prescribed by the act, the insurer is liable therefor.—Kirkoff Bros. vs. McCool (Ind.), 116 N. E. 439.

Issuing Prescription for Intoxicating Liquors—Intent.—An information under the Missouri statute making it an offence to issue a prescription for intoxicating liquors to be used otherwise than for medicinal purposes charged merely the issuance of the prescription which was set out and which was the end of the charge against the physician. It then started off with a separate paragraph and a new sentence to the effect that said liquors were to be used otherwise than for medicinal purposes. This did not charge the physician with that purpose, but covered only the purpose of the person who got the prescription. The information was thought held insufficient.—State vs. Bradford (Mo.), 195 S. W. 523.

Effect of Election of Remedies Against Physician.—Owing to the nature of the relation between a physician and a patient the latter, in the case of a claim of malpractice by the former, ordinarily has a choice of remedies, and may sue the physician either in contract or tort. If he elects to sue in tort, and actually commences and prosecutes his action to a final adverse decision, his right to sue as for a breach of the contract or the breach of a duty imposed by law, by reason of the defendant's calling and the relation between the parties, is lost. And this is true although at the time of the commencement of the action for the tort it was barred by the statute of limitation. The election to sue in tort and the prosecution of such suit to final judgment relates back to the original transaction out of which the action arose, and constitutes an irrevocable election of remedies as they then existed on the part of the patient.—Stokes vs. Wright (Ga.), 93 S. E. 27.

Military Medicine.

LETTERS FROM AN M. M. R. C.

A DOCTOR joining an officers' training camp is apt to be hypercritical of the instructors who lecture. He expects the same ability as that found among most college professors, and in this he will be disappointed. The men from the regular army who are detailed to act as instructors at the various officers' training camps look upon their job as more or less of a bore. Very few of those chosen to fill this position are qualified by experience as lecturers to hold their audience no matter how interested they may be in their work. The principal subject on which they lecture is both dry and complicated, so complicated, in fact, that no one is expected to know it without the text book open before him. "The Army Regulations" and "Manual of the Medical Department of the U. S. Army" are two books which must become part of yourself as soon as active service is started. Although proper form of wording is required for all official communications and reports, no one unaided would be able to dig out from "Army Regulations" exactly what was wanted. The principal instruction given on this "paper work" is the only key to what would otherwise be a mystery. I have before mentioned the absolute necessity for these reports to be correct even to dots and dashes and that they would be returned over and over again by the surgeon general's office with growing sarcastic comment on your ability till they were finally made right by you.

As an indication of when your daily routine of clerical work begins I need merely mention that your morning "sick report" must be in the hands of the adjutant of your regiment at 6.30 A. M. Of course, this does not mean that you have held your daily clinic before this hour. It does mean that so many men have reported themselves to you as being ill and you have set a time later in the morning when you will treat them or else you have sent them to the hospital if they seem very ill. Although illness is looked upon as an unfortunate adjunct to army life, little except absolutely necessary consideration is paid to it. You are taught in your lectures that the only thing that counts in the army is the fighting man power. In time of battle you are told to rush back the slightly wounded first so that their chance of rapid recovery will be greater. Those more seriously wounded where chances of recovery hold elements of doubt must wait till the last for their turn of treatment. Here is a radical difference of viewpoint between the civilian doctor and the army one. If a man appears at sick call and says that he feels desperately ill you make a note of this fact and send him to the hospital. He will be reported as such on your morning report but the man himself will not be examined or receive any treatment, in all probability, till near on to midday. Your clerical and other military duties will preclude much of anything else till this hour. As a warning let me state that the ordinary military hospital found at most of the posts is the last place in the world a doctor wants to be found ill in. The officer of the M. R. C. will receive the same consideration as the poor private in the bed alongside.

At seven o'clock every patient who can get out of his bed must leave the ward till inspection is over. This is accomplished about 9 A. M. If he cannot leave the bed, his extra blanket that was allowed for the night is taken off and bundled regardless, with all the rest, in a closet out of sight. The toilet accommodations are also closed during this hour of inspection. This is rather rough on a man who has taken a dose of salts at 5 A. M. For those that are confined to their beds another pleasant little diversification of the hospital sergeant or orderly is the exact alignment of cots. This is done by a series of kicks, jerks, and pushes till from one end of the ward to the other each cot stands on the exact line. It is an operation that the orderly has his assistant help him in; one sighting down the line and the other doing the "rough stuff." I fancy the sensation must be great for a man who happens to have a raging headache.

To go back to the instructors: The principal theme of all their discourse is literally this: "When you are in the army you must learn to pass the buck!" This is not told you as a joke. It is apparently the real underlying factor in your advancement. By "passing the buck" they mean that you must never be caught being responsible for anything. If at monthly inspection any deficiencies in the surgeon's instrument case are noted by the superior inspector, the doctor who has this case at the time becomes responsible for the loss and must pay for it out of his pocket. There is no delay about this. The Government will take good care to repay itself out of the salary coming to this doctor.

This responsibility is not only for drugs, instruments, and equipment immediately under his control but also applies to all the equipment of the men under him; underclothes, socks, uniform, arms, tent, bedding, and mess equipment. Of course, this officer in turn passes the buck whenever he hands over any equipment to the soldiers of the Hospital Corps. They in turn have to sign and are charged up with anything that is lost or displaced. Reasonable wear and tear is, of course, allowed and is passed on by a board of survey. There is one doctor that I know of who was on the Mexican border recently who is having to make up over four hundred dollars for short supplies that he had been saddled with. If you requisition forty overcoats for your men and there are only thirty-six in the box that comes to you, you are responsible for the lot of forty, unless you had a responsible witness at the time the box was opened to prove that there were only thirty-six in it. Your personal statement that such was the case is of no consideration. If a new sterilizer (say at an original cost of $200) is from any cause destroyed or burnt out through accident which the survey board considered avoidable—the responsible doctor is charged up for a new one. How this system of accountability and responsibility is going to work out on a battle field is to be shortly shown.

Of course, each instructor has a good chance to deliver his own personal viewpoint concerning the Medical Reserve Corps during his lectures. The most virile expression came from one who was assigning a lot of graduates from an Officers' Train-

ing Camp to regimental detachments. It is reported that he bade them farewell in about the following words: "You better forget it at once if you think the Government is under any obligation to you. You are more than repaid for your services with the four or five dollars that you get a day. The Government owes you nothing and you owe it everything. Don't for a second think the Government has to send you or ought to send you on some detail near your home. As a matter of fact, it will probably make a better soldier of you the further you are detailed from your home. In this as in all other matters your personal inclinations will have nothing to do with the case. If you attempt to use pull, and I hear of it, I will do my best to see that you are sent as far as possible away from the place that you wanted!" Naturally, such discourse is extremely disconcerting to the many who have volunteered, and in so doing have not only broken up home and family ties but have given up a paying practice of much over four or five dollars a day. The forty or fifty men who received the above admonition came back looking as if a bucket of ice water had been thrown in their faces. No discourse could have been more indiscreet or more harmful under the circumstances, and certainly none could be better calculated to make the men discontented and possibly to regret the step they had taken.

It is needless to say that the regular army is very short of instructors for the Medical Division. To overcome the situation instructors are now being chosen from the Medical Reserve, who have shown qualification along these lines during their apprenticeship. What the future holds for these new army instructors remains to be seen. Being made an instructor and proving an efficient one of course will put an end to any aspiration to immediate service in France. A beginner at an Officers' Training Camp will find that if he excels in any one subject he is likely to be made instructor in this subject. If you are particularly military looking and learn to drill well it is almost certain that sooner or later you will fill this position as instructor. As in ordinary life, it often does not pay to outshine the average. There are many capable surgeons in the Medical Reserve Corps who now hold positions as Sanitary Supervisors and other such non-operative positions in our forts and camps and will probably continue holding the same till the war is over. If Washington finds that you can satisfactorily fill the shoes of one of its regular men you will surely replace the latter.

Under the present rule of advancement in rank it is reasonably certain that at the end of three months' active service a man may expect to be called before an examining board, and if his efficiency record is satisfactory his name will be recommended for promotion up to the rank of Major. Once a Major always a Major seems to be about the status of this rank. This is somewhat disappointing to the Major who starts as such. If the Government intends drafting doctors they will probably start them at the rank of second lieutenant. After the first raise in rank the second will possibly be more tardy in its eventuation except perhaps in certain cases where there may have been marked service in the field of action.

HEMOGLOBINURIA FROM MARCHING.

THE literature of this subject is very sparse, although the affection is of great interest to the military surgeon. Pari reports a case in the *Gazzetta degli ospedali e delle cliniche* for June 24 which occurred in an infantry soldier aged twenty of previously good health. After marching he complained of backache and passed a dark red urine. He was interned in the barracks hospital for several weeks and then assembled with others at the medical clinic. After the walk of about 3 kilometers he had a second passage of red urine. He was now carefully examined and found to be in fair condition, but somewhat pale. The urine first passed in the clinic was almost black, and analysis showed an uncomplicated hemoglobinuria. The Wassermann test was negative. Subsequent passages of urine were normal. That the condition was not paroxysmal was apparent when it was found that hemoglobin appeared in the urine whenever the patient walked for one or two hours. The Ehrlich test (keeping the feet in cold water) was negative; hence mere cold could be excluded. The orthostatic test—standing for 20 minutes—caused albuminuria, but without hemoglobinuria. The marching test caused slight increase in leucocytes, this being marked in the polynuclear neutrophiles, while the small lymphocytes were notably diminished. The resistance of the red cells was normal. After several weeks of arsenic therapy the march test gave a negative result, although the blood count was altered as in the first count, and on one test albumin appeared in the urine. Apparently this affection need not disqualify from military duty. The nature of the hemoglobinuria in this case at least was obscure, for the results of the cold and postural tests were negative.

Deafness from Corticocerebellar Commotion.—According to Foy in a paper on reaction movements in war otology any deaf soldier who is normal in his middle and internal ears as far as characteristic tests are concerned and is suspected of exaggeration or simulation may be regarded as a victim of neuropathic or commotional deafness if he presents disturbances of peripheral sensibility and abnormal reaction movements, whether spontaneous or induced. These include movements with closed eyes, induced movements of the head, nystagmus of various kinds, etc.; the most recent and valuable being Moure's staff test, in which with eyes closed and head inclined the suspect turns five or six times around an upright pole, then stops, opens his eyes, straightens his head, and marches a few steps straight ahead. Under this test a normal subject will deviate to the side of rotation, while the inexcitable subject goes straight ahead. A hyperexcitable subject will all but fall. In such deafness recovery is quite possible.—*Revue de Laryngologie.*

Prat's Gangrene.—Tieves refers to the rigidity of the muscles in certain traumatized limbs which appears to herald the appearance of gangrene and cites cases in which this stiffness was present in the muscles below the site of injury and persisted until the evolution of the gangrene. The mech-

anism is not difficult of comprehension because the rigidity is clearly the result of ischemia from injury to some bloodvessel higher up. This absence of blood then is due to the same cause as the necrosis of the extremity which it precedes (pregangrenous myoischemia). Only in theory can this condition undergo involution. All cases described have been as final as rigor mortis. Conservative surgery is very venturesome in such a condition and therefore amputation is the treatment. Prat was the first to call attention to this symptom.—*Paris Medical.*

America Medica Somnolenta.—How soon will the medical profession of the United States, as a whole, wake up and realize that doctors must come forward and volunteer their services to the Government? In civil life, when great casualties occur, the doctor readily offers his services and usually is the first on the scene to save human life. How much more important is it, then, that in this critical situation, he should come forward and offer his valuable aid to preserve not only human lives, but the life of the nation itself? Application blanks for commissions in the Medical Reserve Corps are being printed in many medical journals [see MEDICAL RECORD, July 21, August 18 and 25] or will be sent by the Surgeon-General's Office, or can be secured from members of the Local Board of Examiners.—*Boston Medical and Surgical Journal.*

For Ambulance Hospital on Russian Front.—Plans are being actively pushed for the establishment of an American Ambulance in Russia. One of the ventures for raising funds for this purpose was the building of grand stands and the sale of seats for the farewell parade of the National Guard on August 30.

Red Cross Shipping Service.—In order to handle the quantities of relief and medical supplies that are being shipped to the Red Cross Commission in Europe the Red Cross Transportation service has been inaugurated. The new service is made possible by the cooperation of the French, British, and Italian Governments, the United States Shipping Board, and the leading steamship and railroad companies. From now on practically all the cargo space the Red Cross needs will be found for it, many lines carrying this freight without charge. A. C. Fetterolf, freight traffic manager of the Mercantile Marine Company, has been named manager of the ocean shipping and will serve without salary.

Centralization of Relief Work.—The American Relief Clearing House which was established in Paris shortly after the outbreak of the war is to be succeeded by the American Red Cross for France and Belgium in an effort to organize and coordinate the work in these countries. The officers of the new branch are: Major Grayson P. Murphy, Commissioner for Europe, and James Perkins, assistant.

American Army Takes Over Ambulance Work.—Steps have been taken for the transfer of the American Field Service with 1,100 men in the ambulance branch, and 800 in the transport branch, by the American Army. The ambulance branch is to go under the control of the medical service and the transport under that of the Quartermaster General. Representatives of the medical service have gone to visit the thirty-four ambulance sections along the front and invite the men to enlist for the duration of the war under the same conditions of service as are now existing. Henceforth any man who wants to drive an ambulance must enlist as an ordinary private in the hospital corps by application to the Surgeon General in Washington.

Relief Mission to Serbia.—The War Council of the American Red Cross announces the sending of a commission to Serbia to begin relief work. The War Council has appropriated $200,000 for the purchase of medical and other supplies that will be needed among the refugees of Macedonia. A special appropriation was made for the purchase of milk and 48,000 cans of condensed milk have been purchased. It is estimated that 150,000 fatherless families in various parts of that country are facing destitution. Cordenio Arnold Severance of Minneapolis heads the commission. The deputy commissioners are: Dr. Severance Burrage, sanitarian, formerly of the Massachusetts Institute of Technology; Dr. Frederick T. Lloyd, physician, of Boston; Dr. Eugene A. Crockett, surgeon, of Boston; Fater Francis Jager, University of Minnesota, Minneapolis, and Edwin D. Haskell, secretary, Minneapolis.

Favor Cancellation of Physicians' Leases.—The Rotary Club of Chicago has found that a great many physicians who have entered the service are embarrassed by unexpired leases and believes that such leases might better be waived during a time of national peril like the present. They have written letters to 20,000 American physicians in an effort to set on foot a movement to secure legislation, looking to the abrogation of leases of members of the Medical Reserve Corps.

Work of the Russian Red Cross Commission.—The Red Cross has authorized the publication of a cablegram from Dr. Frank Billings, head of the commission. This dispatch says that already they have established a big working headquarters and a supply house. The mission has been most cordially received by the Provisional Government and is now in active co-operation with the sanitary department of the Army and with the Russian Red Cross, and is about to get in touch with the zemstovos and unions, these three associations being the great relief organizations of Russia. In response to a request from Dr. Billings, the American Red Cross is sending large quantities of medical and surgical supplies to meet the urgent need of the Russian military hospitals.

The commission carried with it $200,000 worth of such material, including among other supplies more than 50 microscopes and 45,000 slides, 4,600 clinical thermometers, 288 operating knives, 23,000 lengths of catgut, 1,700 ice caps, 175,000 morphine sulphate tablets, and 200,000 antiseptic tablets.

In the new consignment, for which the war council appropriated $160,000, there are 180,000 tablets of quinine sulphate, 1,000 pounds of chloroform, 10,000 tablets each of atropin and strychnine for hypodermic injection, 50,000 doses of anti-typhoid vaccine, also tetanus anti-toxin and diphtheria, smallpox, cholera and plague vaccine, 10,000 pounds soap, 25 dozen hot-water bottles, 10,000 pounds of gauze dressings and pads, 10,000 bandages and rolls, 1,000 blankets and

6 dozen stethoscopes, and various laboratory supplies.

The shipment also includes 5,000 c.c. of digitalis, 1,000 cocaine tablets, 20 collapsible operating tables, 14,400 needles, 200 pounds rubber tubing, 20,000 pounds absorbent cotton, 5,00(safety pins.

Plan School of Brain Surgery.—The joint committee on ophthalmology and oto-laryngology of the Medical Board, after making a canvas of 150 large hospitals of the country in order to learn how many men were specializing in brain surgery and sending a similar letter to the leading neurologists of the country, held a conference at which a general plan for the organization of a section on brain surgery was discussed. A tentative plan has been outlined for the establishment of schools for the instruction of surgeons classified in the brain surgery section. If necessary these schools can be established in Chicago, Baltimore, New York and Philadelphia. Each school will be under the direction of a skilled brain surgeon. The course will be arranged along a clinical, anatomical, and operative line, and will extend over a period of from four to six weeks. A plan to secure good laboratory work in connection with the operative work of the brain surgery is under consideration. This branch of the service is considered most important, not only from the standpoint of the soldier but because of the neurological material which will have a great scientific value if properly preserved. This committee is collecting a list of names of physicians for the position of surgical assistant in brain surgery, and who are also capable of doing neurological laboratory work.

Activities of the Committee on Ophthalmology.—The Council on National Defense authorizes the announcement that its committee on ophthalmology has been engaged in activities directed to the perfection of plans for doing this special work. An investigation has been made of the ophthalmologists in the Medical Reserve Corps, who are available for ophthalmological work and who may be called upon for active duty. In order to prevent the introduction of trachoma into the Army a group of specially qualified ophthalmological surgeons has been selected for the purpose of examining all suspected cases of this disease. Tests for the detection of malingerers claiming visual defects have been selected and submitted for approval and also a list of eye instruments for use at base hospitals. Plans have been prepared for the utilization of one ward at each cantonment hospital for eye examinations.

Oral Surgeons Wanted in Army.—In the field of oral surgery special arrangements have been made whereby men of large experience and ability in general surgery in conjunction with dental oral surgeons will do much of the oral surgery. Such an arrangement as this has been made necessary because of the limited number of experienced oral surgeons and the unwillingness of men of really large experience in surgery to limit themselves to strictly mouth surgery. In view of these facts the following proposition has been submitted: "That surgeons in charge of oral surgery, shall, unless otherwise specified in individual instances, have charge of injuries and surgical diseases of the mouth and its essential structures, including the bony structure and soft parts of the face and also of the neck when the major part of the injury is situated above the clavicle. Provision is made that when injuries of these regions require the special attention of laryngologists, oto-rhinologists, oculists, or neurologists, such special advice will be available. The average oral unit will properly consist of an operator competent to do major surgery and his assistants, a dental oral surgeon with more or less special training, and an ordinary dental practitioner. The Joint Committee on Head Surgery requests that names of any men specially qualified along the lines just outlined be presented to the committee for consideration.

Dr. James S. Brown of Montclair, N. J., who has been active in Red Cross work, has been commissioned Major in the Medical Reserve Corps.

Dr. Dubaouchet, formerly chief surgeon of the American Ambulance, has been commissioned Major in the United States Army.

National Society to Train War Cripples.—The National Society for the Promotion of Occupational Therapy met on the land ship *Recruit*, on September 2, to discuss ways and means of training crippled soldiers so as to fit them to resume their former occupations or to train them for new ones. Those who have investigated the re-educational schools of France and England say it is almost impossible for a man to be so badly crippled that he cannot be trained with the aid of artificial limbs to some occupation. The society elected P. W. Jackson president, and Mrs. Winifred Brainerd chairman of the executive committee.

Fatalities in Battle.—The Committee on Public Information has obtained from official sources the most nearly accurate figures possible on the percentage of fatalities in relation to casualties on the western front. These figures, taken when the casualties were greatest in proportion to mobilized strength and combined with the highest proportion of deaths, show losses due to deaths from wounds and killed in action to be approximately 11 in every 1,000 of mobilized strength. According to the figures presented by the French High Commissioner in his letter to the Secretary of War, the high-water mark of casualties in the French Army was reached early in the war—at the battles of Charleroi and the Marne. The casualties in that period were 5.41 per cent. of the mobilized strength, or 541 men in every 10,000 with the colors. Military experts in this country agree that the killed in action and died of wounds have never at any time in this war exceeded 20 per cent. of the total casualties. This gives a figure of 108.2 fatalities from these causes in every 10,000 mobilized strength, or practically 11 men killed in action or died of wounds for every 1,000 men with the colors.

Ambulances for Red Cross.—The Ford Motor Company has donated credit amounting to $500,000 worth of automobile ambulances, parts, and the like, which the Red Cross may designate. This gift is considered particularly valuable in view of the responsibilities assumed by the Red Cross for the support of the American Red Cross in France.

BLOOD PRESSURE IN THE AGED.

THE trouble with generalities is that they are too general. Thus the saying that a man is as old as his arteries, while it bears a certain amount of truth, must not be accepted too unreservedly. Nevertheless, the question of blood-pressure becomes a more and more important one as the span of life draws near the allotted three score and ten. and this should not be estimated by a casual feeling of the pulse on one side, a glance at tortuous temporals, or the patient's account of vertigo, headache, etc. The most accurate methods available must be used and their results interpreted by the most modern knowledge of the subject.

In this connection two recent articles by Dr. L. M. Bowes (*Journal of Laboratory and Clinical Medicine*, Jan. and June, 1917) may be quoted. He studied three hundred and eleven cases, all but two of the patients being between sixty-five and ninety-five years of age. In the first of the two articles, Bowes calls attention first to the technique and the necessity for taking readings of both sides, as they usually vary considerably, especially in arteriosclerosis, although it must be borne in mind that the pressure may be low in this condition, if chronic myocarditis is supervening. Bowes further concludes that high systolic pressure associated with high diastolic pressure, indicates cerebral hemorrhage or nephritis; a sustained hypertension, both of systolic and diastolic pressure, indicates cerebral hemorrhage, while hypotension means cerebral embolism; a sustained high systolic with a low diastolic is suspicious of cardiac trouble, especially aortic regurgitation; a high pulse pressure is frequent in arteriosclerosis and aortic regurgitation and a sustained high pulse pressure usually results in a failing heart; a systolic pressure of one hundred may not keep a man from his daily business; lowering blood pressure means failing heart, and acute enteritis lowers blood pressure.

In his second paper the author gives the results of his studies of diastolic pressure. When this was high (above 95) he usually found some abnormal condition,—cerebral hemorrhage, mental symptoms, valvular heart disease, or the like. The diastolic pressure may be raised or not in arteriosclerosis, depending on the heart and kidneys. He found it low in aortic regurgitation and chronic myocarditis. Bowes studied fifty patients who had been hard smokers for from forty to seventy years, but was not able to determine that this habit had the effect on the blood-pressure which is popularly supposed. He found some old men who had been inveterate smokers all of their lives who had a systolic pressure of from one hundred and sixty to one hundred and ninety mm. and diastolic pressures of from eighty to ninety. The writer lays especial stress on the diastolic index which he says may prove of great value—in surgery, for example, just before the amputation of a limb.

These studies remind us that, in spite of a wealth of casual allusion to the subject, too little use is made of the sphygmomanometer in daily practice. A careful examination of both the systolic and diastolic pressures of both sides of the body and interpretation of these results in the light of such work as this of Dr. Bowes, may aid greatly in diagnosis and prognosis. One fact in its favor is that it is not too difficult a diagnostic method for every-day use.

INTRAVENOUS INJECTIONS OF FOREIGN PROTEIN AND PEPTONE IN TYPHOID FEVER.

THE favorable influence in the course of typhoid fever of the intravenous injection of typhoid vaccines has been known for several years. The idea is growing, however, that this influence is not due to specificity but to the mere presence in the blood of foreign protein. It is possible to abort the disease outright, but the reaction provoked may be so severe as to be more deadly than the disease. Mauté, a Morocco physician, was imbued with the idea that a nontoxic protein injected slowly and cautiously could be made to influence favorably the course of typhoid without any untoward results. An abstract of his paper will be found on page 257 of the MEDICAL RECORD and it will suffice to state here that he employed dead cultures of a harmless saprophyte. The results obtained were not unlike those which follow intravenous injection of suspensions of colloidal metals.

Quite independently of this line of activity Professor Nolf of Liège (*Archives Médicales Belges*, February, 1917) has been making an extensive trial of intravenous injections of peptone in typhoid fever. A solution of these bodies when thrown rapidly into a vein causes an anaphylactoid shock and hence its use in medicine has usually been discountenanced. Nolf succeeded in proving that by very deliberate injection of peptone into a vein the pharmacodynamic action was the reverse of that heretofore obtained, while the action on the course of typhoid much resembled that of the dead, "inert" culture used by the Moroccan. The question is raised as to the nature of the active substance which is present in peptone as well as in albumin proper.

Whether or not this plan of treatment will ever come into general use is perhaps beside the mark, but it has been shown by these experiments that after the disease is about ten days old an intravenous injection will depress the fever to a greater or lesser extent for about forty-eight hours or more, when a second injection may be made and so on until the normal period of defervescence is anticipated or reached. In especially favorable cases something like an abortive effect is seen. In some other cases the patient may be kept almost fever free so long as the injections are continued. In the less favorable cases the fever curve is kept down so that the mean daily temperature is much lower than what would be normal for the case. There seems to be a difference in the activity of the two types of injection. The action of peptone seems to have been sharper but shorter; that of the culture was much slower, both in the descent and in the subsequent rise. Hence a second injection of the culture was sometimes sufficient to break up the fever curve entirely. In a few cases a single injection alone caused permanent defervescence. It is possible that the presence of paratyphoid cases gives the narration a more favorable coloring than would appear in selected cases of true typhoid.

SPECIFIC TREATMENT OF LEISHMANIASIS.

THE general belief of the practitioner has been hitherto that a specific remedy can apply only to a single clinical entity and that there can be but one specific for a disease. This, of course, is purely an *a priori* conception, for to-day we realize that in a given affection due to bacteria several substances could be efficacious as microbicides not only in the particular affection but in others which perhaps have little in common with it.

In an article on the specific treatment of leishmaniasis by Dr. Fernández Martínez, which appears in the *Gaceta Médica Catalana* for July 15, the adjective specific appears to relate to a group of remedies which have shown specific value in other well known affections. Some of these are quinine, arsenicals, mercury, and antimony. All attempts to cure kala-azar with serums and vaccines seem to have failed. On the other hand, cures are claimed for a number of drugs, including the above. Recoveries have even been credited to the action of iron. On the other hand, many patients go on to death, the disease being uninfluenced by treatment of any sort.

Tartar emetic has been claimed as a specific for all the leishmaniases, but is also asserted to be a quasispecific for other affections due to microparasites, for example granuloma venereum, and, we believe, certain trypanoses. Moreover, it is said to be as efficacious locally in lesions of the surface as when given internally. This form of curative activity should perhaps be termed quasispecific.

The author claims some remarkable results in kala-azar from intravenous injections of tartarized antimony, a remedy which is also curative in leishmaniasis americana (espundia). In Oriental sore local treatment is added. Failure of the antimony treatment the author would accredit to error in diagnosis. Before he had used antimony Martínez got some very good results from cacodylate of iron, but in some of these cases relapses occurred. As already implied, not a few other remedies have temporarily cured or greatly benefited individual cases of kala-azar. Wine of antimony also gave good results. Two questions remain to be answered: First is antimony free from danger? It has been accused of causing severe renal disease. Second, is an antimony cure permanent or will some of these cases relapse in time or become reinfected? Some evidence points to acquired immunity, other data to acquired susceptibility. The author in summing up seems to hold a mental reservation about the free use of a drug like antimony. He suggests that autovaccination may yet prove to be at once the harmless and curative remedy which is desired.

MILK AND THE HEALTH OF CHILDREN.

IT is certain that, at the present time, when maternal feeding of infants appears to have fallen into disrepute, the condition of the milk supply is one of our most important public health problems. As Dr. C.-E. A. Winslow pointed out in a paper read before the annual meeting of the Ontario Health Officers' Association and published in *Canadian Practitioner and Review*, August, 1917, the normal infant can usually manage to get along even with poor milk in winter, and it can endure a high summer temperature if fed at the breast. It is the combination of putrefactive bacteria in its food and high atmospheric temperature which undermines its vitality and leads to serious and so often fatal results. Clean milk and safe milk are by no means synonymous terms, because milk is so easily infected. There is no such thing as an absolutely safe milk supply, and according to Winslow and many other authorities, milk designed for infants' use, even if procured from undeniably hygienic sources and safeguarded from pollution and infection in the most elaborate manner, should always be pasteurized. Even if by this process certain vitamines normally present are destroyed, it is better that their loss should be replaced by orange juice or some other container of vitamines than that the infant should be subjected to the menace of an infected or polluted milk supply. Furthermore, it must always be borne in mind that pasteurized milk itself must be guarded, as it can easily become infected; also that pasteurization should be carried out scientifically and carefully. Otherwise it but engenders a false confidence and may be the means of spreading disease even more widely than if the process had never been performed.

SYNTHETIC ALCOHOL.

ALCOHOL can be obtained by a variety of syntheses and chemical reactions, but thus produced it is far more costly than alcohol distilled from grain, pota-

toes, etc. As a result of the war, the scarcity and rapid increase of cost of grain have made it necessary to resort to syntheses, one of which seems to be sufficiently unexpensive to allow of further unlimited conservation of grain. In the *Correspondenz-Blatt für Schweizer Aerzte* for July 21, Fleissig briefly outlines a process already in use in Basle. Calcium carbide is obtained in great quantities for various industrial purposes by expelling the CO_2 from limestone in a kiln. The calcium oxide left behind is now heated in the electrical oven with coal and the resulting expulsion of carbon monoxide leaves calcium carbide intact. If water is allowed to drop into that substance acetylene gas is formed. Acetylene plus water yields aldehyde (acetic aldehyde); to obtain this reaction a catalyser is required and mercury sulphate is usually selected for the purpose. If now aldehyde is hydrogenized in the presence of certain metals (nickel, platinum), alcohol is formed. The ingredients for this synthesis of alcohol comprise respectively limestone, water, coal, and electrical energy, for other reagents can all be made (save the catalysers) from the basic ingredients (H and O from the electrolysis of water). To make a ton of alcohol one needs 2500 kg. of coal and 4000 kg. of limestone. To make a ton of grain alcohol by distillation, 11,000 kg. of wheat are necessary. The discovery, if the method is practical, should be welcome not only to the munitions makers but to the medical profession as well, because the lowered cost of alcohol (also incidentally of acetic acid) will cheapen the production of many useful drugs, such as chloroform and formaldehyde.

Dr. Osler's Loss.

THE most heartfelt sympathy of the medical profession of America goes out to Sir William Osler on learning of the death of his only son from wounds received in a recent engagement in Flanders. The young man, Edward Revere Osler, who was born twenty-one years ago in Baltimore, was a second lieutenant in the British Army.

News of the Week.

Medical Students to Complete Their Studies.—In response to the urgent appeals of physicians and medical instructors, a supplemental regulation has been drawn up, with President Wilson's approval, permitting medical students and hospital interns to complete their studies and exempting them from service in the ranks. The following telegram explaining the new regulation has been sent by Provost Marshal General Crowder to the governors of the various States:

"Hospital interns who are graduates of well-recognized medical schools, or medical students in their fourth, third, or second year in any well organized medical school, who have not been called by a local board, may enlist in the enlisted reserve corps, provided for by section 55 of the National Defense Act, under regulations to be issued by the Surgeon General, and if they are thereafter called by a local board they may be discharged on proper claim, presented on the ground that they are in the military service of the United States.

"A hospital intern who is a graduate of a well-recognized medical school, or a medical student in his fourth, third, or second year, in any well-recognized medical school, who has been called by a local board and physically examined and accepted, and by or in behalf of whom no claim for exemption or discharge is pending, and who has not been ordered to military duty, may apply to the Surgeon General of the army to be ordered to report at once to a local board for military duty, and thus be inducted into the military service of the United States immediately, to be discharged from the national army for the purpose of enlisting in the enlisted reserve corps of the medical department. With every such request must be inclosed a copy of the order of the local board calling him to report for physical examinations, affidavit evidence of the status of the applicant as a medical student or intern, and an engagement to enlist in the enlisted reserve corps of the medical department.

"Upon receipt of such application with the named inclosures, the Surgeon General will forward the case to the Adjutant General with his recommendations. Thereupon the Adjutant General may issue an order to such intern or medical student to report to his local board for military duty on a specified date, in person, or by mail or telegraph, as seems most desirable. This order may be issued regardless of the person's order of liability for military service. From and after the date specified such person shall be in the military service of the United States. He shall not be sent by the local board to a mobilization camp, but shall remain awaiting the orders of the Adjutant General of the army. The Adjutant General may forthwith issue an order discharging him from the military service for the convenience of the Government.

Present Prevalence of Poliomyelitis.—A recent Public Health Report states that occasional cases of poliomyelitis are reported from all parts of the country. This has been so for a number of years. During the present summer, however, the only localities in which the reported prevalence of the disease has been such as to indicate the presence of outbreaks are: Washington County, Vt., where 53 cases were reported during June and July; Haverhill, Mass., where, from June 1 to August 22, 31 cases were reported; New Castle, Pa., where there were 29 cases reported during the same period; Alleghany County, Md., where 23 cases were reported; Marion County, W. Va., Rockingham County, Va., Belmont County, Ohio, and Pope County, Minn., have also reported slight outbreaks of this disease.

United States Civil Service Examinations.—The United States Civil Service Commission announces an open competitive examination for experts in the prevention of infant mortality, for both men and women. There are vacancies in the Children's Bureau, Department of Labor, at salaries ranging from $2,400 to $3,600 a year, with actual traveling expenses and a per diem allowance in lieu of subsistence while absent from headquarters on official business. The duties of appointees will be to plan and conduct investigations into the causes of infant, child, and maternal mortality in selected communities, to inquire into the methods of their prevention, etc. Graduation from a medi-

cal school of recognized standing, and at least three years specialization in the hygiene and diseases of childhood, or in the prevention of infant and child mortality by public or private agencies, are prerequisites for consideration for these positions. The Civil Service Commission also announces an open competitive examination for experts in child welfare, at salaries ranging from $1,800 to $2,400 a year. These positions are open to men and women. The prerequisites for consideration for these positions are an educational training at least equivalent to that required for a bachelor's degree from a college or university of recognized standing, including two or more years' special training in sociological or industrial subjects, and at least three years' experience in professional sociological or industrial investigation, or in journalistic or literary work, including the writing of special articles primarily relating to sociological or industrial questions. Another competitive examination, for women only, as assistants in the prevention of infant mortality, is announced. These positions carry a salary of $1,800 to $2,400 a year. The duties of the appointees will be to assist in conducting rural and urban community investigations. The requirements are graduation from a school of nursing connected with a general hospital having a daily average of thirty or more patients, and a continuous hospital training of not less than two years. The applicant must have had eight months' study at a school of recognized standing, giving postgraduate work in public health or visiting nursing, and at least two years in infant and welfare nursing or in public health or visiting nursing. Applicants for any of these positions should apply for form 2118, stating the title of the examination desired, to the Civil Service Commission at Washington, D. C., before September 18, where further information may be obtained.

Medical and Surgical Relief for Injured Civilian Employees of the United States Government.—Under the terms of the Federal Compensation Act of September 7, 1916, civil employees of the United States, when injured while in the performance of their duties, are entitled to "reasonable medical, surgical, and hospital services and supplies" for the injury, whether or not disability has arisen. Section 9 of this act provides that, where practicable, such services and supplies shall be furnished by United States medical officers and hospitals. Officers in charge of works where there are United States medical officers and hospitals available for this purpose are requested to inform all employees that such services are available to them in case of injury. An official statement just issued reminds all United States officers in charge of dispensaries that such dispensaries should furnish as complete medical and surgical service as possible, and to promote this service the commission will pay the necessary carfare of injured employees who are able to return to the dispensary for treatment. In places where there are United States medical officers, hospitals, or dispensaries other than the United States Public Health Service, and it is practicable to utilize their services for the treatment of injured civil employees, the commission should be notified of this by the United States officers in charge of the works upon which civil employees are engaged. In places where there are no United States medical officers, hospitals or dispensaries, the commission approves the selection by the injured employees of reputable physicians licensed under State laws to practice medicine or surgery. In places in which there is no United States hospital, provision is also made for the care of injured employees in a general hospital as ward patients.

Examination for Medical Assistant, District Attorney's Office.—The Civil Service Commission of the State of New York announces an examination for the position of Medical Assistant, in connection with the District Attorney's Office of Kings County. Applicants must have been residents of Kings County for at least three months prior to Sept. 26, 1917, and must be physicians or surgeons for at least ten years duly licensed to practice medicine in this State. The duties include the examination of the dead body and of all the premises where it is found for the purpose of ascertaining all the facts which will aid in the elucidation of the time and circumstances surrounding the death; and ascertaining by autopsy such facts as may be shown relative to the cause of death, and also assistance to the District Attorney in preparing the case for trial. The office of the position carries with it a salary of $4,000 a year. For application forms and other information application may be made to the Civil Service Commission, Albany, N. Y., not later than Sept. 26, 1917.

Dr. W. H. Dale, formerly of Harrisburg, Pa., has been appointed to succeed Dr. Harry E. Clay as member of the State Board of Health of Oregon.

The Tri-State District Medical Society of Iowa, Wisconsin, and Illinois held its annual scientific and clinical meeting in Dubuque, Iowa, Sept. 4, 5, 6, 1917, under the presidency of Dr. William B. Peck of Freport, Ill.

Health Department to Regulate Private Laboratories.—The Board of Health of New York City has added a new section to the Sanitary Code, in accordance with which "No laboratory offering facilities for the diagnosis of communicable disease shall be conducted or maintained in the City of New York without a permit therefor issued by the Board of Health or otherwise than in accordance with the regulations of said Board."

County Hospitals for Tuberculosis Mandatory in New York State.—At the recent session of the Legislature a law was passed as a war measure so that the State will be prepared to treat cases of tuberculosis discovered in examining drafted men or those found in the army itself, making the establishment of county tuberculosis hospitals mandatory in New York State. The Board of Supervisors of every county in the State, containing a population of 35,000 or more, shall establish a county hospital for the care and treatment of persons suffering from tuberculosis. Each county hospital shall be available for patients on or before the first day of July, 1918. Contracts for tuberculosis hospitals must be awarded by January 1, 1918. This law affects twenty counties, eight of which had previously taken steps toward the erection of a hospital. The State Charities Aid Association has published a pamphlet consisting of a compilation of the laws of the State relative to county hospitals which may be obtained upon request by addressing the State

Charities Aid Association, 105 East 22d Street, New York City.

State Makes Low Mortality Record.—Although the population of New York State has increased more than 67 per cent in the last quarter of a century, there were fewer deaths in July, 1917, than in July, 1892. Had the rate of 1892 prevailed during July, 1917, there would have occurred 12,000 more deaths than actually did occur. July was formerly one of the months that showed highest mortality; it has now become one of the healthiest of months, largely due to the reduction in the infant mortality. From a total of 2,237 infant deaths due to diarrhea in July, 1910, the number of such deaths declined to 1,133 in 1913, and in July, 1917, to 437 deaths, one-fifth the number of deaths from this cause only seven years ago. This is reflected in an infant mortality rate of 70 per 1,000 births in contrast with the July rate of 186 per 1,000 births in 1910. Accidental injuries and deaths have shown very little tendency to decrease. Thus far this year there have been reported 5,103 fatal injuries in the State, or 700 more than the average for the last five-year period. The increase in accidental fatalities has been chiefly due to automobiles.

Public Health and Food Administration.—An advisory committee on public health has been appointed to aid the conservation division of the United States Food Administration. It is composed of the following members: Drs. W. H. Welch, chairman; Leonard P. Ayer, Herman Biggs, D. L. Edsall, Cary T. Grayson, W. Hewlett, T. C. Janeway, F. G. Novy, R. Pearce, and H. Gideon Wells.

Obituary Notes.—Dr. DOUGLAS MACROBBIE, a practitioner of Hamilton, Ontario, met a violent death on August 20. He was a graduate of the University of Toronto, in 1896, and was 45 years of age.

Dr. GEORGE HIRAM MATSON of Columbus, Ohio, for eleven years secretary of the State Medical Board of Ohio, dropped dead on August 21, presumably of heart disease. He was a graduate of the Ohio Medical University, Columbus, in 1905, and also a graduate of the College of Pharmacy of the Ohio State University, in 1892.

Dr. N. FAY TILTON, a graduate of the Ohio Medical University, Columbus, in 1901, and a practitioner of Marion, Ohio, was killed in an automobile accident. He was a Lieutenant of the Medical Reserve Corps and president of the Marion County Medical Society.

Dr. JOHN ORLANDO ORR died suddenly at his home in Toronto on August 22, aged 56 years. He was a graduate of the University of Toronto, in 1884, and afterwards studied at Kings College, London. He was a member of the British Medical Association, the British Laryngological Society, and the Dominion Medical Association. In 1903 he became manager and secretary of the Canadian National Exhibition.

Dr. JOHN H. TARBOTTLE, formerly connected with the State Hospital at Dayton, Ohio, a graduate of the Starling Medical College, Columbus, Ohio, died on August 18 as the result of injuries sustained in an automobile accident.

Dr. SKIDMORE HENDRICKSON, for 25 years a practicing physician of Brooklyn, died at Monsey, L. I., on August 20, aged 76 years.

Correspondence.

MILK SICKNESS AND TREMBLES CAUSED BY RESIN OF WHITE SNAKEROOT.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the *Ohio Naturalist*, 1906, I set forth the evidence which led me to the conclusion that the disease known as trembles in cattle, sheep, and horses was a poisoning caused by their eating the white snakeroot. Later, Mr. Crawford of the Bureau of Animal Industry, after some experiments in feeding aqueous extracts of this plant, concluded that it was not the cause of trembles, and criticised my work in a bulletin published by the U. S. Department of Agriculture. Recently the North Carolina Experiment Station has taken up the question again and fed white snakeroot to sheep. This has verified my claim that this plant is the cause of the trouble. The publication by the U. S. Department of Agriculture mentioned above prevented the general acceptance of my conclusions, excepting in Ohio. For example, L. H. Pammel of Iowa in his book on "Poisonous Plants of the United States," after quoting from my article in the *Ohio Naturalist*, adopts the conclusion of Crawford.

It was not until ten years after the publication of my article that any experiment station made a thorough test of the effects of feeding white snakeroot to sheep or other animals. I hope that it will not take another ten years for the results of these experiments to become generally known throughout the extensive region where people and domestic animals are suffering and dying from this disease; nor ten years before the North Carolina or some other Experiment Station will investigate the claim I now make that the constituent of white snakroot responsible for the poisoning is a resin. My earlier impression that the poisonous constituent of the plant was aluminum phosphate (see article in the MEDICAL RECORD May 15, 1909) was an error which I have disproved by a long series of experiments. Aluminum is more common in plants than the books of botany had led me to think, and I have even found small amounts of it in the blood of a steer and of a sheep which I had no reason to think were diseased.

By means of a Soxhlett extractor I have made quantitative determinations of the ether extract in many samples of white snakeroot, the material having been gathered in different localities and different years. Last fall I gathered leaves of this plant from woods which had served as pasture for cows whose milk and butter had caused milk sickness in all three members of a family, the daughters having recently died from it, the mother who was seriously ill surviving until late in the winter. Leaves from these woods yielded ether-extract to the extent of about 9 per cent. of their dry weight; nearly all of this extract was resin.

The extract when taken with food by rabbits affects them as they are affected by eating white snakeroot. Fed to a guinea pig, it produced similar effects, but the animal was killed by a dog before the experiment was completed. Cats will not ordinarily take enough of the resin to kill them, although they may be induced to take enough to show some of the symptoms characteristic of trembles.

The melting point of the resin is about 100° Fahr. When it is poured on shelled corn that is stirred while warm, the kernels receive a thin coating of resin, and rabbits will continue for a number of days to eat corn that has been treated in this way, or the resin for them may be put on zwiebach or lettuce or cabbage. Much green feed probably tends to diminish the effect of the resin by preventing or lessening constipation.

The resin has a pronounced effect on the kidneys and produces a general passive congestion of the small intestine and various other organs.

E. L. MOSELEY.

NORMAL COLLEGE,
BOWLING GREEN, OHIO.

RESEARCH WORK INTERRUPTED.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the fall of 1916 I was requested by the Commissioner of Health, through Dr. Park, director of the bureau of laboratories, to investigate the effect of alcohol upon the life processes of warm-blooded animals, including man. After a thorough reading of the voluminous literature on the subject, a series of well-planned and well-controlled experiments were made, and a preliminary report stating that small quantities of alcohol had apparently no deleterious effect was submitted to the Commissioner.

The commissioner's zeal for prohibition apparently gained over his discretion and devotion to scientific ideals, for I was not allowed to publish the results of my scientific research; I was not only prevented from completing my research, but was asked to hand in my resignation. Upon my refusal to do so, charges of "disobedience" were preferred against me and I was dismissed while on my vacation, all records of my experiments having disappeared in the meanwhile.

I leave it to the members of the profession to pass judgment upon such doings. My colleagues in New York City, with whom I have come in contact as chief of the Whooping Cough Clinic and as consultant in the Meningitis Department, will, I trust, make their protest heard in defense of the freedom of scientific research, which is the basis of medicine.

PAUL LUTTINGER, M.D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEDICAL EXAMINATIONS AND REEXAMINATIONS.

LONDON, Aug. 4, 1917.

A SELECT committee is inquiring into the conduct of medical examinations, more especially of re-examinations. Sir Ryland Adkins, giving his experience, said he felt they were not working out in a way to give the tribunals the assistance they would like. They were faced with remarkable contrasts in the classifications of persons brought before them. When we have men rejected in the autumn of 1915 and again in August last coming before us with a constant record from private doctors of A or B1, it is difficult to know where duty lies. He found the difficulty greater since the act authorizing re-examinations. We know doctors are men of ability, devotion, courtesy and good-will; but we know also that they are overworked, and often, if not always, obliged to do things too quickly, and that therefore their results are wanting in weight. His impression about complaints of tearing up of certificates was that though he would be the last to credit every such story, it was impossible to sit on a tribunal week after week and listen to them without concluding there must be some ground for them. One remedy, he suggested, would be that medical men of fifty years old or upwards should sit upon the board, two-thirds of which should consist of experienced local practitioners. No single doctor should pass a decision of his own accord. He further referred to the raising of men from low to high categories with "almost inexplicable quickness," and declared this had a bad effect upon public opinion, as did also the fact that presidents of boards could over-rule the decisions of other members. Asked if complaints had been made of examinations being too rapid and cursory, he replied yes, in many cases, and on further inquiry it was found there was something in this, though not so much as had been suggested. He could not throw any light on war-office statistics, which showed nearly 60 per cent. passed it in March, as against 20 per cent. in August. Out of thirty-eight men passed for general service and sent to the Special Medical Board seven were rejected and the remainder placed in a lower category. These should have a right to have their cases reconsidered, but how the exigencies of war would allow that he did not know. He could throw no light on war-office statistics. Instances of the uncertainty of Medical Board decisions were reported. In one a man passed but was reexamined on appeal and exempted. In another, the man was passed in October, but when called up the following June was found unfit. He had meantime sold his business at a considerable loss. Another man, after joining the Army Service Corps, was found unfit on account of mitral disease in one of its worst forms. Referring to the complaints, the chairman pointed out that a man might be maimed for life by negligence of the examiner, and suggested that a record should be kept of the doctor responsible for passing a man, so that he could be identified.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

HEADQUARTERS ARMY MEDICAL DEPARTMENT—TREATMENT FOR WHOOPING COUGH—NEW TREATMENT FOR PLEURISY—THE MINERAL SPRINGS OF FRANCE.

PARIS, August 6, 1917.

THE medical and commissary departments of the Headquarters Staff have removed from the building at 27 rue Constantine to a hotel in the rue Ste. Anne, having rented the entire building. It took only a week or two to demonstrate that the original location was much too small to accommodate all of the departments.

Colonel Bradley, Chief of the Medical Department, has been almost constantly out upon inspection tours, choosing hospital locations near the front, and the press of work kept the clerical force working at all hours, until quite recently, when five o'clock was set as the quitting hour and Saturday half holiday was inaugurated at the same time.

My attention was recently arrested by an article in the *Paris Médical*, Feb. 3, advocating a very old remedy for whooping cough administered in a new way. The author advocates the administration of the tincture of drosera between meals, ten drops for each year of age, three times a day, augmenting the dose rapidly by three to five drops each time until the initial dose has been tripled. The remedy is well tolerated by the stomach. The author has arrived at a dose of 400 to 600 drops of the remedy in 24 hours without causing any inconvenience. In infants he gives the same number of drops as the child is months old, three times per day, augmenting the dose by two drops each administration until arriving at 120 drops a day. The only adverse symptom observed from these massive doses is at times some nervous excitability, which he attributes to the alcohol of the tincture. The author claims that this remedy reduces the violence and frequency of the coughing paroxysms and noticeably the frequence, oftentimes to one-quarter of the daily number prior to the treatment, and the vomiting ceases nearly always, which is of great importance in nursing infants. He also claims that the remedy will almost at once relieve spasm of the glottis.

Professor Tuffier, at a recent meeting of the Academy of Medicine, reported a series of cases of purulent pleurisy and extravasations of blood into the pleura which had become purulent. After having exposed the technique of his procedure, which consists in evacuating the pleural cavity, introducing the Carrel irrigating tubes and sterilizing the inflamed surfaces until all infection is shown to be absent by the microscope, then closing the pleural opening to heal. Dr. Tuffier gives the result in twelve cases thus treated, ten of which were purulent. All were cured, but the remarkable feature of the cure was that the lungs recovered all of their functional activity, which infrequently follows the other forms of treatment.

The incalculable burdens put upon the future generation by the monstrous ambitions of Germany can in a degree be appreciated only by those who have come into intimate contact with the horrors of this war. We believe, without exception, everyone possessed of this knowledge feels that Germany should be punished in every department of her national life, and France is awakening to the fact that the prevalence of this idea in the minds of the Allied nations forms an exceptional opportunity for her to put forth an organized effort to attract to her shores universal patronage for the various lines in which she has heretofore found Germany to be the most active and most successful competitor.

Estimated from an American standpoint, I do not think that the French can be called successful advertisers. They are too self-satisfied; they believe the attraction of Paris and the country is a sufficient advertisement for themselves and this has nowhere been more clearly exemplified than in the treatment of her mineral springs and health resorts. While Germany has been advertising her springs and watering places all over the world and particularly in the United States, attracting thousands annually, France has allowed hers to pursue the quiet order of their ways, their virtues to be discovered by those who chance to visit them; but there is a promise that all of this will be changed. Various articles have recently appeared in the medical press, looking to arouse the profession and the public to the need of concerted action to formulate some plan of campaign to attract the American traveler to the watering places of France. The Prince of Monaco has donated 800,000 francs for a Congress of Hydrology and Climatology to meet at Monaco at the close of the war, and it is the intention of the French delegates to make this the starting point of an organized propaganda to make known to the world the wonderful wealth in variety and excellence of her mineral springs, for which she has no superior in the world.

2. Studies in Infant Feeding.—A. W. Bosworth and H. I. Bowditch present a study of the mineral constituents (ash) of milk. They state that in most, if not all, of the methods of modifying cow's milk for infant feeding, the mineral elements present receive very little attention, being passed over with the statement that modified cow's milk will always contain a larger percentage of ash than breast milk, and hence will furnish all the mineral elements necessary. The time has come, however, when this phase of the feeding problem can no longer be treated in this manner, and more care must be taken to see that the mineral elements are properly balanced. While bottle-fed infants receive an excess of mineral elements, they retain a much smaller percentage of the minerals ingested than do breast-fed babies. This is due to the fact that these elements, as they are present in cow's milk, are not completely available for food for infants. This fact has been demonstrated by experiments now being made by the authors. It has been shown by one of the authors that, while dicalcium phosphate is a normal constituent of cow's milk, it is not a constituent of human milk. As this salt has always been found in large quantities in the feces of infants fed upon cow's milk, and is absent or present in very small amounts in the feces from breast-fed infants, an investigation was made of the availability of this mineral salt as a food. When infants were fed a synthetic milk in which the only inorganic salt present was the dicalcium phosphate, from 64 to 100 per cent. of the salt fed was recovered, the smaller recovery being in infants from eight to nine months old, and the complete recovery from infants one to four months old. These investigations have also shown that under ordinary conditions any excess of soluble calcium received in the food is precipitated in the intestines as calcium carbonate or insoluble calcium soaps, and is not available as food, and that the addition of lime water to milk, although increasing the actual calcium content of the milk, really brings about a precipitation of insoluble calcium phosphate, leaving amounts of soluble and available calcium and phosphorus which are less than those to be found in breast milk, a fact which should receive more attention in connection with the feeding of certain children, as, for instance, those having rickets, spasmophilia, etc. It has been the general practice to consider the quantity of mineral elements present in the milk to be represented by the ash. The amount of the ash—about 0.7 per cent.—has usually been considered as containing all the mineral elments in the milk, and the figures obtained by the analysis of such an ash have been quite generally accepted. Such an analysis does not represent the true mineral content of the milk, for under

conditions ordinarily surrounding the determination of ash some of the sulphur and phosphorus in the casein molecule will be lost by volatilization. If this loss is taken into consideration the true mineral content of cow's milk of average composition will be found to amount to 0.8 per cent. of the milk. As the result of extended studies the writers give a detailed statement of the forms in which the mineral elements are to be considered as being present. On the basis of these analyses it would seem that the good results obtained in the feeding of eiweiss milch are due to the fact that the available mineral content of this milk approximates very closely both in form and quantity that found in breast milk.

3. Basic Principles in the Symptomatology of Bright's Disease.—H. Elwyn deplores the confusion in current literature on Bright's disease due to the description of a multiplicity of types. He states that Volhard and Fahr in their monograph on Bright's disease have demonstrated that there are three elements of the kidney to be considered, namely, the tubules, the glomeruli, and vessels of the kidney. After reviewing the symptomatology in connection with these elements he suggests the following classification: Tubular nephritis may be classified into acute tubular nephritis or nephrosis, and chronic tubular nephritis or nephrosis, both with or without amyloid deposit, and the special form of necrotic tubular nephritis or nephrosis, of which the sublimate kidney is the prominent example. The affections of the vessels of the kidneys may be either a benign sclerosis of the kidney vessels or benign hypertension, and the malignant form of kidney sclerosis, or malignant hypertension, or a combination form. The writer believes that by classifying Bright's disease in this way and by a knowledge of the principles underlying the symptomatology of these forms, one gets a better view of the prognosis and definite indications for treatment.

4. Cellular and Humoral Factors in Anaphylaxis and Immunity.—Wilfred H. Manwaring, Arthur R. Meinhard, and Yoshio Kusama present an analysis of the anaphylactic and immune reactions by means of the isolated mammalian heart and the isolated mammalian lungs. These tissues can be readily perfused free from circulating blood, and tested under controllable serological conditions. These perfusion experiments have shown that in anaphylactic and immune animals there are four essential factors: (1) Cellular anaphylaxis, or the hypersensitive condition of the fixed tissue cells; (2) cellular immunity, or the increased resistance of the fixed tissues; (3) humoral anaphylaxis, or the toxin producing power of certain normal and anaphylactic blood elements; and (4) humoral immunity, or the antitoxic power of certain immune blood elements. The analyses have further shown that these factors may coexist in the bodies of anaphylactic and immune animals in the following combinations: (1) Cellular anaphylaxis and apparently normal blood condition. This is illustrated by the four week anaphylactic guineapig. The lungs tested in the presence of normal blood are thrown into a typical anaphylactic response. The blood perfused through normal lungs produces no immediately recognizable reaction. (2) Cellular anaphylaxis and humoral anaphylaxis. This is illustrated by the fourteen day anaphylactic guineapig. The lungs, freed from anaphylactic blood, are markedly hypersensitive. The blood perfused through normal lungs produces an immediate typical reaction. (3) Cellular anaphylaxis and humoral immunity. This seeming paradox is illustrated by the lungs of immunized guineapigs. Freed from immune blood, the lungs are markedly hypersensitive. The blood, perfused through anaphtylactic lungs, prevents a reaction. (4) Cellular immunity and humoral anaphylaxis. This second seeming paradox is illustrated by the heart of the anaphylactic rabbit. This heart, freed from anaphylactic blood, is distinctly resistant to a primary toxic protein (active foreign serum). The blood, perfused through a normal heart, produces a typical anaphylactic reaction. (5) Cellular immunity and humoral immunity. This is illustrated by the heart of the immune rabbit. The heart is distinctly resistant. The blood prevents a reaction in the normal heart. (6) Humoral anaphylaxis and humoral immunity. This third seeming paradox is illustrated by the blood of partially immunized rabbits, which contains a thermolabile anaphylactic element, partially neutralized or held in check by a thermostable immune element. (7) Cellular anaphylaxis and cellular immunity. A fourth seeming paradox is illustrated by the heart of a sensitized rabbit. Tested in a blood free condition, this heart usually shows an increased resistance to a primarily toxic protein (active foreign serum) and at the same time an acquired susceptibility to a nontoxic protein (inactive foreign serum). From their observations the writers believe that it will probably be necessary to reduce anaphylactic and immune reactions to lower physiological terms than those at present employed, before seeking to apply current immunological theories.

7. Local Anesthesia in Sixty Cases of Acute and Chronic Appendicitis.—Joseph Wiener says he has been using local anesthesia in more and more acute cases of appendicitis and thinks that peritonitis, far from contraindicating performance of the operation under local anesthesia will gradually become an indication for this operation. When we consider that the system is already struggling to throw off a peritoneal infection, and that the organs of excretion are doing a large part of this defensive work, the danger of handicapping these organs still further is apparent. Of the sixty cases which furnish the basis of this communication, forty-one were chronic and nineteen were acute. The acute cases included empyema of the appendix, gangrene, large abscess of the appendix and two cases of well marked peritonitis. Including both the acute and chronic cases the average time of operation was twenty-two minutes. Postoperative distention was strikingly absent in most all of the cases, and the writer considers this one of the great advantages of local anesthesia. With the exception of the peritonitis and abscess cases, nausea and vomiting were almost uniformly absent in these cases. The average stay in bed including both acute and chronic cases was a little less than seven days. The local anesthetic consists of the following: Threequarters of an hour before operation the patient receives a quarter of a grain of morphine hypodermically. Just before operation this dose is usually repeated, unless the patient appears drowsy from the first injection. A one per cent solution of novocaine to an ounce of which twenty drops of 1:1,000 solution of epinephrin have been added is used. Tablets of novocaine with epinephrin are a great convenience. The writer dissolves five one-grain tablets in an ounce of water and this suffices for the complete operation. He finds the postoperative course in these cases in striking contrast to what we see in cases that have had ether. A few hours after the operation there is little wound pain, which is easily controlled. Peristalsis is usually established early. Almost all the patients have been able to take and retain fluids within a few hours after the operation. There is an entire absence of the mental depression so common after ether. The writer says he intends to use this method in an ever increasing number of cases, and believes that in not a few cases it will actually be life-saving.

2. **The Importance of Diet as a Factor in the Production of Pathological Changes.**—William Salant discusses the rôle that diet plays in the causation of disease and refers to different lines of inquiry furnishing evidence of its growing importance in pathology. That diet as a factor in the causation of disease is not confined to the so-called deficiency diseases is suggested by the results of pharmacologic investigations which have been brought to light within the past few years, for it has been shown that a definite relation exists between diet and pathological changes produced by well defined chemical substances, such as acetonitril, caffeine, chenopodium, and tartrates. The writer states that Rieger and he have frequently been impressed by the difference in the reaction to caffeine which was exhibited by dogs receiving different amounts of protein. A high protein diet, it was found, was conducive to increased resistance to this drug. In experiments on the toxicity of chenopodium carried out on different animals it was found that fatty oils modified the action of this substance. The toxicity of the oil of chenopodium for cats and rabbits which had received cottonseed or cocoanut oil was diminished at least 50 per cent. in some cases. Rabbits fed on carrots resisted much larger doses of the tartrate than those which received oats and cabbage. Further investigations made more recently on the toxicity of this substance shows that the resistance of the animal was very markedly increased when carrot leaves were fed from four to eleven days before injecting tartrate. A high degree of resistance to tartrate was also shown when sweet potatoes were fed. A dose of 2.0 per kilogram failed to produce nervous symptoms or furnish evidence of renal irritation. Sodium tartrate proved to be most toxic when the diet consisted of oats. Experiments with tartarate on cats that received different diets failed to show any marked difference, but it may be remarked that in these animals the toxicity was markedly increased in starvation, which was also noticed in rabbits. That protection is also afforded by diet against the injurious effects of some of the heavy metals was furnished by the results of experiments with zinc malate. Small quantities of this salt given intravenously to rabbits produced marked albuminuria in twenty-four hours. Rabbits which were fed on carrots for some time previous to the injection of the zinc malate exhibited a decidedly greater resistance to zinc poisoning. Studies were also made as to the effect of diet on the permeability of the kidneys in tartrate nephritis. These indicate that the injury to the kidney caused by this salt varies considerably with the diet. From 0.2 to 0.3 gm. of sodium tartrate given subcutaneously may retard the elimination of phenolsulphonephthalein to a very considerable extent in rabbits when fed oats alone. The amount of dye eliminated had decreased by a half to two-thirds about five hours after the administration of 0.2 sodium tartrate per kilogram. When carrots alone were given for three or four days previous to the injection of tartrate, and if this diet was continued for some time after the injection of the tartrate, renal permeability remained quite satisfactory. The effect of this diet was noted even when the dose of the tartrate was doubled. The writer does not intend that the evidence he has presented shall be taken as a warrant for generalization, but believes this subject is full of promise of valuable results to medicine.

6. **The Constitutional Disturbances That Come With Chronic Goiter.**—Charles N. Dowd. (See MEDICAL RECORD, June 16, 1917, p. 1072.)

8. **A New Operation for Movable Kidney.**—Willard Bartlett describes this operation which he has used on 20 patients, 19 of whom have been followed for periods varying from a few months to five years. These bear evidence to the permanency of the results. The other patient died suddenly on the ninth day after the operation. The operative technique is divided into the following six steps: (1) With the patient lying on the left side I have employed the incision of my old teacher, von Bergmann, which bisects the angle formed by the last rib and the outer edge of the erector spinæ. (2) As soon as the abdominal cavity is opened, all the fat is removed from the inside of the posterior abdominal wall, leaving the muscles perfectly bare in the kidney fossa, the object being the ultimate formation of broad adhesions between the kidney surface and these denuded muscles. (3) The fatty capsule of the kidney is divided longitudinally with the entire of the organ and caught with clamps at several points. The exposed kidney is lifted out of the abdomen, and at the same time the fatty capsule is inverted over on to the pedicle, being divided to a considerable extent above so that when the kidney lies completely outside the wound edges the inverted fatty capsule occupies a position beneath its lower pole. (In some cases the fibrous capsule will adhere to the kidney very firmly, while in others it will tend to move with the fatty envelop; hence no definite rule can be formulated which will always govern the treatment of this structure. In the majority of cases, it has been left undisturbed. (4) With a needle and catgut, the cut edges of the fatty capsule which were originally grasped by clamps are united, thus transforming this inverted structure into a rather considerable ball of fat, which in most instances is about half the size of the kidney itself. (5) This ball of fat now constitutes a pedunculated flap and is transposed into the defect into which the kidney formerly slid. To insure its remaining in the desired location, it is anchored to the inner aspect of the abdominal wall directly under the lower angle of the wound by a stitch of the catgut which was used to unite its component parts into one spherical mass. (6) The posterior abdominal wall is completely closed in layers without drainage. By this procedure three objects have been accomplished: (1) The self-lubricating lining of the extraperitoneal cavity has been removed. (2) The cavity itself below the kidney has been filled up. (3) The bared kidney and bared muscles of the posterior abdominal wall are definitely opposed to each other for adhesions to form.

4. Notes on the Drainage of an Infected Hemothorax. A. Neville Cox.

2. **A Contribution to the Microscopical Histology of Malaria.**—Leonard S. Dudgeon and Cecil Clarke were led to make this investigation because during an epidemic of malaria in the Salonica Army in 1916 sudden death was not uncommon, and the committee which was appointed to inquire into and report on the fatal cases noted that a large proportion of the patients died within twenty-four hours and no less than 57 per cent. died within the first two days of admission to the hospital. Further, collapse and even sudden death occurred as an initial phenomenon of this disease. The observations presented include the cerebrum, cerebellum, medulla, heart muscle, adrenal glands, liver, spleen, kidneys, and intestinal tract. Examination of the heart showed, in addition to fatty degeneration, blocking of the capillaries with infected red cells in most instances. The microscopical changes in the adrenal gland were very numerous. The most constant alteration from the normal histology was the diminution in the lipoid substances. This loss occurred in all layers of the cortex. The chromaffin substance in the medulla was also greatly reduced in amount. The cerebrum, medulla, pons, and

cerebellum were examined from three cases and in all three the lesions were both severe and widespread. In each case the patients died in coma. Thrombosis was present and was more marked in the white matter. The spleen, liver, and kidneys showed extensive fatty degeneration with areas of necrosis. Thrombosis of the capilaries and arterioles in many of these cases was a striking feature. In those specimens in which thrombosis of the vessels was present foci of necrosis predominated. The hepatic changes were numerous. The deposit of pigment, which has long been regarded as a constant characteristic of malarial fever, was present in every case. The bile examined in some of the fatal cases of malaria by Captain Clarke was found to be sterile, and in thirty-five cases at a mobile laboratory the authors found the blood sterile in every case. Captain Elworthy in one of the laboratories in Salonica made blood cultures in eighteen cases of proved malarial fever with negative results in each instance, while samples of the bile in eight fatal cases of malaria and cultures from the spleen in six cases were found to be sterile. The widespread changes occurring in the tissues and the rapid spread of the infection in so many cases on the one hand and the cardiovascular phenomena on the other have led some to believe that this outbreak of malaria is different from all others. It has been suggested that this difference depends on the virgin soil which has been placed at the disposal of the parasites, or on the parasites, or on the quinine. The writers recall Sir Ronald Ross's remarks that "some authors consider that there are two, if not three, varieties or species of malignant malarial parasites" with which they feel disposed to agree.

3. **Treatment of Tuberculous Eyes by Local Application of Tuberculin.**—Henry A. Ellis and H. M. Gay observe that tuberculous affections of the eyes seem especially prevalent in children. In the cases coming under the authors' notice every superficial part of the eye and appendages has been found to be tuberculously infected. The large proportion of girls affected—thirteen boys to twenty girls—suggests that dust is domiciliary rather than external. All the thirty-three cases so far treated have proved curable in any time from six weeks to three months, and so far only one relapse has occurred among cases in which the treatment has been completed. The treatment consists in instilling tuberculin into the conjunctival sac directly, in various dilutions of increasing strength. First in every case the cutaneous test is made on the forearm. This not only aids in the diagnosis but records the susceptibility of the patient to tuberculin. Cases are by this means classified into definite classes: (1) Hypersensitive, giving a marked reaction to a solution of tuberculin from 1 in 500 to 1 in 10,000; (2) sensitive, reacting doubtfully to 1 in 500; (3) subsensitive, giving a marked reaction to 1 in 10 T; (4) insensitive, giving either no reaction or a very slight one. Tuberculin should be used differently in each of these types as would naturally be expected. As a rule the cutaneous reaction in eye cases demonstrates that they belong to the sensitive and hypersensitive classes, as would be expected, since they generally belong to the group of double infections. The authors describe the dosage in each of these classes of cases.

2. **On Gunshot Injuries of the Chest, with Special Reference to Hemothorax.**—John Rose Bradford discusses more especially the cases observed from the third or fourth day up to about three weeks after the occurrence of the injury. Hemothorax is the most common result of a chest wound, both pneumohemothorax and pneumothorax being relatively rare. In a series of 328 cases of gunshot wounds of the chest only eight cases of the former and four of the latter were observed. In a study of the morbid anatomy of wounds of the chest made by Henry and Elliot in a series of 100 cases observed in a base hospital in France, dealing only with cases that succumbed from the third day to the third week, one of the most striking facts ascertained was that within these limits of time death from hemorrhage as a result of a wound of the chest was very rare. In a series of seventy-eight fatal cases of simple hemothorax there were seventy in which either infection or an additional visceral complication, or both, were present. In the remaining eight cases in which death might have been due to hemorrhage, purulent bronchitis was present in three, and in four cases no record existed as to whether sepsis was present or not, thus leaving but one case in which hemorrhage alone could be definitely asserted to be the cause of death. Septic infection is therefore by far the most frequent, and heretofore the most important cause of death in cases of hemothorax that survive the first few days immediately following the wound. Secondary hemorrhage is also extremely rare, there being only three such cases recorded in this series of 100 cases. In the treatment of sterile hemothorax, if the amount of bloody fluid is small there is no need for any special active treatment. If the effusion is at all large early aspiration may be required to relieve the distress. The fluid should be removed by aspiration about the end of the first week. Aspiration with oxygen replacement is better than simple aspiration. Further, with oxygen replacement practically all the fluid in the chest can be removed at one sitting. For practical purposes it is not necessary to measure accurately the intrapleural pressure; it is sufficient to regulate the introduction of oxygen by the presence or absence of symptoms. Free drainage is required in all cases of infected hemothorax, and it is of the utmost importance that this should be provided as early as possible as the organization of the deposit of lymph on the visceral pleura produces a great impediment to the rapid expansion of the lung after the removal of the fluid, and this organization proceeds rapidly in cases in which delay in operating takes place. Removal of the infected fluid by free drainage is, however, not sufficient treatment in all cases; the inflammation in the pleural sac and the septic clots must be treated by the local application of some efficient antiseptic applied either by periodical washing out of the cavity or else by the instillation method and the Carrel-Dakin technique. Recently the latter method has been applied with success to cases of infected hemothorax, and a few cases have been so successfully treated that the operation wound for the excision of the rib has been closed by secondary suture before the evacuation of the patient for England.

4. **Dermatitis Due to Explosives Used in Air Raids.**—Dr. J. H. Sequeira has previously called attention to a form of dermatitis caused by handling powder from high-explosive bombs and aerial torpedoes. He states that he has now seen fifty-nine cases of dermatitis of this kind and that they all fall into two groups. The clinical picture is distinct. The initial staining is nearly always of a distinct orange tint, especially well seen on the palms of the hands. After the lapse of nine days, as a rule, the patients complain of intense irritation and itching, which interferes with sleep. This is followed by the appearance of closely set discrete vesicles the size of hemp seeds. These are on the palms and along the sides of the fingers and in the interdigital clefts. In many cases huge confluent blebs form. In a few instances the lesions rapidly become infected and pustules form. The eruption is at its height about the fourth or fifth day, and the epidermis gradually separates, leaving a raw, rather dry, red surface. In some instances the feet were affected after the hands, probably being infected from the hands. Occasionally the face is also involved. In three cases submitted to bacteriological examination the *Staphylococcus epidermidis albus* was found in one instance, and the *Staphylococcus pyogenes aureus* in another. In several cases in which a blood examination was made there was a marked eosinophilia. As a prophylactic measure, it is important to avoid touching the powder or material impregnated with the powder. Its removal from walls or other surfaces can be effected by moistening the surface with a weak solution of

sodium bicarbonate (one teaspoonful of sodium bicarbonate to a quart of water). When the eruption has developed the hands should be washed as little as possible, but the alkaline solution may be used without risk. The best local application is a liniment of calamine (calamine 70 grains, lime water 1 ounce, and olive oil 1 ounce). In a septic case daily spraying with malachite-green sublimate solution is of great value. The substance which is the cause of the dermatitis appears to be hexanitrodiphenylamine.

La Presse Médicale.

July 23, 1917.

The Infundibular Syndrome in a Tumor of the Third Ventricle.—Claude and Lhermitte refer to the fact that the hypophysis is not an "excitable" organ and that the socalled syndrome produced by its excitation really proceeds from the interpeduncular area. The following case is related in a mechanician on a submarine who was known to have suffered from syphilis and paludism. On admission to a neurological service he appeared sickly—pale and thin. He was completely off his food and very asthernic. At night he was much troubled with thirst. On physical examination he was apparently 100 per cent. sound but he complained of amblyopia and in addition to polydipsia showed polyuria. The association of these symptoms with visual disturbances led to lumbar puncture with practically negative results. A special eye examinatoin led to the diagnosis of simple bitemporal hemianopsia. Everywhere the research for clean cut signs of organic disease met with negative results. An equivocal lymphocytosis and albuminosis in the spinal punctate suggested a possible syphilitic basilar meningitis involving the chiasm and tuber cinereum; the patient was placed on intensive mercurial treatment. A few days later there developed cardiac arrhythmia with muffling of heart sound. This was in turn followed by speech disturbances which suggested pseudobulbar paralysis. Both classes of symptoms soon vanished and were followed by various sleep disorders—narcoleptic seizures with amnesia of a retrograde type. A careful neurological examination gave only negative results. Next in order was a recurrence of the cardiac syndrome with tachycardia and embryocardia. To this succeeded an attack of complete amaurosis. At this juncture the patient was found to have tuberculosis of the right apex. Confusional delirium was now added to the picture. Despite his serious condition he developed a mental state of euphoria which persisted to the last. For about a month he was free from symptoms aside from polyuria and several attacks of narcolepsy with alternations of visual acuity. Death took place as a result of tuberculous bronchopneumonia. Autopsy showed a normal hypophysis and sella. The lesion in the case appeared to be an epithelial cyst of the third ventricle.

American Surgeons and Hysterectomy for Cancer.—Tayle refers to the belief in America that Ries preceded Wertheim in devising the operation known by the latter's name. Ries of Chicago actually read his initial paper in 1895 before the Frankfort Medical Society and this paper appeared promptly in a German journal. In April and May of the same year John G. Clark of Philadelphia performed a radical abdominal operation for cancer and his paper appeared in the Johns Hopkins Hospital Bulletin for that year. In 1896 Kelly and Clark reported 8 cases of this radical abdominal operation. Hence not only Ries but Clark preceded Wertheim by over 3 years, for the latter did his first radical operation in 1898. Those who might look upon this essay of priority as hastily inprovised are referred by the author to Cullen's great work on cancer of the uterus in which the whole matter is threshed out. For this book was composed during 1898-9 and while the work of the pioneer Americans is given in full, Wertheim is not mentioned simply because his work was not yet on record (his first article appeared in 1900).

Il Policlinico.

July 1, 1917.

Lumbar Puncture in the Treatment of Certain Forms of Essential Cephalalgia.—Mingazzini, the neurologist of Rome, has been testing the efficacy of lumbar puncture for several years in essential headache. It is of course known on all sides that this resource will at times relieve headaches due to increased intracranial tension from miscellaneous causes. In a series of 24 cases he has cured patients of habitual paroxysmal headache. Most of them were women in the childbearing period who suffered from recurrent headaches with marked constitutional reaction—evidently false migraine. In some cases headache was so severe as to produce mental confusion. The author was careful to exclude syphilis and the wine drinking habit in excess. The punctate was normal as a rule with tension but slightly increased. To select a few cases at random, patient No. 25 was a married woman aged 35, never pregnant, who drank daily a tumbler of wine. In 1911 she had been operated on for gastronephroptosis. Cephalalgia began in 1914 and appeared early in the day, lasting for 24 hours or more. There were associated disturbances of vision which at times induced hallucinations. Neurological examination was negative. After a series of lumbar punctures she made a good recovery. Patient No. 50 was a girl of 15 who drank daily one glass of wine. Morning headaches had appeared at puberty. Neurological examination negative. Punctate normal, no increased tension. One puncture seems to have cured the patient. Most of the women patients, however, took no wine at all, so that a slight indulgence could hardly have been a factor in causing the headache. A survey of the material shows considerable variety in the type of headache despite the uniformly favorable results of puncture. For example, in one there was a history of nephritis. In a second series of 15 cases there was no cure but much relief; the patients were of much the same type—women at or near the childbearing period with negative neurological examination. Finally in a third series of 8 patients puncture gave no relief whatever although the material was of the same type as in the favorable series. The author analyses his subject to an extreme extent in an attempt to set up a theory of cause and cure. Of 47 patients treated but 6 were males. We may use the expressions essential headache and persistent headache (whether these appear daily or with longer remissions) but it is evident that we are dealing only with a symptom. We know that lumbar puncture undertaken for other symptoms may cause headache outright. Complete failure to relieve habitual headache by puncture opens up a host of possibilities—of cerebral syphilis, tumor of the brain, etc., but also of neuralgia or the action of some toxic principle on the meninges. Of great suggestiveness is the borderline increase of albumin and leucocytes in the punctate which may suggest an inflammatory factor.

Treatment of Gonorrhea with Hot Baths and Dakin's Solution.—Duncker combines Weiss's vapor bath principle with injections of weak Dakin's fluid. Instead of the vapor bath, however, which may or may not raise the body temperature to 42° C. (a temperature at which the gonococcus cannot survive) he places the patient in a hot bath of 47° or 48° C., keeping him under water for fifteen minutes. Protargol injections, when used, are heated to 42° or 43° C. Infusion of camomile or uva ursi was added in equal volume to Dakin's solution. While in individual cases an abortive effect was obtained the average duration of treatment was cut in half. The technique is somewhat complicated and could hardly be employed offhand. The temperature of the bath water is raised very gradually, under pulse control (pulse should not exceed 130-140). It may be necessary to lift the feet out of the tub and support them on a board.—*Nederlandsch Tijdschrift voor Geneeskunde.*

Treatment of Nervous or Essential Insomnia.—Lesieur and Peuret state that chloral should be reserved for a different class of conditions—eclampsia, tetanus, restlessness after cranial wounds. Nearly all hypnotics contain the ethyl radical (C_2H_5) in combination with elements of varying toxicity. One of the most promising of these, because least toxic, is malonylurea. A combination of the two is at once broken up in the system into urea and CO_2. The full name of the substance is diallylmalonylurea. Like some notable predecessors in the field it is at present sold as a proprietary. It is said to cause sleep, after a dose of 1 to 2 decigrams, in thirty minutes or less.—*Le Caducée.*

Book Reviews.

CATARACT; Senile, Traumatic and Congenital, by W. A. FISHER, M.D., Professor of Opthalmology, Chicago Eye, Ear, Nose and Throat College. Price, $1.50. Chicago: Published by Chicago Eye, Ear, Nose and Throat College, 1917.

THE volume is one of 109 pages profusely illustrated. The work is devoted to a discussion of the relative value of the various operations or the extraction of cataract, to a description of the Major Smith operation and of the Author's modification of the Smith operation. Statistics of operative results are given and a strong plea is made for the adoption of the method as practiced by the writer. The book should be read by all who practice ophthalmic surgery.

HUGHES' PRACTICE OF MEDICINE. Including a Section on Mental Diseases and One on Diseases of the Skin. Eleventh Edition Revised and Enlarged. By R. J. E. Scott, M.A., B.C.L., M.D., Fellow of the New York Academy of Medicine; Fellow of the American Medical Association; formerly Attending Physician to the Demilt Dispensary; formerly Attending Physician to the Bellevue Dispensary; Author of "The State Board Examination Series;" Editor of "Witthaus' Essentials of Chemistry and Toxicology," "The Practitioner's Medical Dictionary," Gould and Pyle's "Cyclopedia of Medicine and Surgery;" etc., etc. With 63 illustrations. Price, $3.00 net. Philadelphia: P. Blakiston's Son & Co., 1917.

THAT this book has lived so successfully to reach its eleventh edition shows that its basis of assumption that diagnois and treatment are the main business of the practitioner, is indeed a correct one upon which to thrive and grow.

The editor, while retaining prescriptions and forms of treatment tried and known to be sound, has in some instances rejected the old—but very conservatively—and introduced the new in therapeutics, where it has seemed advisable to do so. The editing of an eleventh edition speaks for the correctness of his judgment. Articles on the lately known diseases, or more lately worked up, such as syphilis, Rocky Mountain spotted fever, acute febrile jaundice, erythremia, and milk sickness have been brought up to the last word in medical research; while important additions have been made to material on color index of the blood, blood pressure, Coleman's high calorie diet in typhoid and other fevers. Brudzinski's sign, the use of vaccines, and the period of quarantine for most of the communicable diseases. Also the vitamine theory of rickets is given, showing the extent of research and practical knowledge offered in a condensed form to both students and physicians.

DISEASES OF THE STOMACH. A TEXTBOOK FOR PRACTITIONERS AND STUDENTS. By MAX EINHORN, M.D., Professor of Medicine at the New York Post-Graduate Medical School and Hospital; Visiting Physician to the German Hospital. Sixth Revised and Enlarged Edition. Price $4.00. New York: William Wood and Company, 1917.

SINCE the first edition of this book, which made its appearance about twenty years ago, great advances have been made in the pathology and treatment of gastric conditions. Running through six editions, this work has naturally been brought exactly up to date in every phase of stomach troubles. A sense of amazement steals over the reader at the amount of space allotted to nervous affections of the stomach. This must mean one of two conditions: either the medical profession is more alive to the presence of neurotic causes in the development of gastric and systemic conditions, or these conditions must be decidedly on the increase as the causes of physical disablement among people who are forced to seek aid from stomach specialists. This last indicates that life, through its stress and strain, is producing these nervous states. Thus a vicious circle is formed. The greater the development of the causes, the greater the amount of treatment necessary to overcome the conditions. Can the stomach specialist, let alone the general practitioner, offer much hope to these individuals so suffering? Is it in his power to so control the life of the individual that peace and harmony may exist between the man, his stomach and his environment? Another circle formed. Can one replace the other? Perhaps the stomach specialist, more than any other barring the neurologist realizes the benefit of common sense psychology when brought into play with this type of cases thus bridging over the two circles, if not completely replacing one by the other, and producing a partial readjustment of conditions in that most distressed spectacle of humanity—the dyspeptic American.

The subject of diet is given about twenty-eight pages of thoughtful consideration in this work. One wishes that the author had devoted more space to so very important a foundation both for pathology and treatment of stomach conditions. The illustrations chiefly illustrate different types of apparatus to be used in this specialty. One feels like offering a sincere expression of sympathy to the individual, who, suffering from enteroptosis, is compelled to wear some of the styles of abdominal bandages thus portrayed.

The book is attractively published covering every requirement demanded from both publisher and printer.

A TEXT-BOOK OF FIRST AID AND EMERGENCY TREATMENT. By A. C. BURNHAM, M.D., Medical Corps, U.S.R.; Instructor in Surgery in the Polyclinic Hospital, New York City; Attending Surgeon, Department of Surgery, Vanderbilt Clinic, College of Physicians and Surgeons, New York City. Illustrated with 160 Engravings and Two Plates. Price, $2.00 net. Philadelphia and New York: Lea & Febiger, 1917.

ANOTHER First Aid to the Injured! The land will soon be full of them! This one, however, merits just consideration because it is beautifully illustrated, although it must be admitted that some of the pictures bid fair to bring chills of fear to the female portion of the first-aid contingent. The text is well written, but in sections seems a bit ambiguous. Thus on page 48 the author, in describing the course of the aorta, leaves it to the imagination of the reader as to whether this artery turns to the front of the chest and passes over the stomach, or whether in true orthodox fashion it follows its usual natural course and wends its way down the spinal direction. The description of the general circulation beginning on page 49 is one of the best the reviewer has ever had the pleasure to read in a first-aid book. Just sufficient is given to convey a correct picture to a struggling first aider, and only those who have taught first aid know the awful struggle the study of the heart and circulation occasion to men and women who sometimes do not even know the locations of their stomachs. On the whole the book is most satisfactory, for it is really a compend on both first aid with a touch of nursing.

CLINICAL STUDIES IN EPILEPSY. By L. PIERCE CLARK, M.D., Consulting Physician, New York City Children's Hospitals and Schools, Randall's Island; Letchworth Village for Mental Defectives, and Craig Colony for Epileptics. Utica, N. Y.: State Hospital Press, 1917.

So much has been written about epilepsy that a new book must inevitably shoulder the burden of proving its right to exist. Various schemes of classification, ingenious etiological theories, bewildering therapeutical displays, verbose characterological estimates, prolix case-reports, all these have been done over and over again in the literature. Dr. Clark has cut this Gordian knot with his psychological sword. He has approached the epileptic and his symptoms in a new way. He has studied the personality problem involved and tried to see why the convulsion occurs and what it means to the individual. In a former thesis he held that there is a definite epileptic constitution, hypersensitive and egotistical, and that the convulsion represents a reaction away from the difficulties such a character inevitably experiences in contact with society; it is a psychobiological phenomenon, doubly motivated. In his present monograph Clark enlarges somewhat upon this thesis, illustrating it by detailed studies of cases. He also describes tentative efforts at therapy based on this conception. Dr. Clark is a pioneer in this field; whether or not it is one which will be fruitful to the extent he anticipates cannot be foretold. Certain of his theorizing is perhaps a bit too fine spun—he has reacted himself too far away from reality. But better a thousand times such an approach to this problem than the eternal stagnation of the "nervous discharge," the bromides, etc.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-ninth Annual Meeting, Held at White Sulphur Springs, W. Va., May 28, 29 and 30, 1917.

THE PRESIDENT, DR. FRANK SPOONER CHURCHILL OF CHICAGO, IN THE CHAIR.

(*Concluded from page* 393.)

A Case of Congenital Heart Disease. — Dr. CHARLES HUNTER DUNN of Boston reported this case. He said that in this child the presence of a palpable systolic thrill, of persistent cyanosis, and of cardiac enlargement, suggested the presence of pulmonary stenosis. The fact that the child survived for fifteen months suggested the existence of some additional compensatory lesions, either defective ventricular septum or patent ductus arteriosus. The diagnosis in the case was pulmonary stenosis, defective interventricular septum, chronic intestinal tuberculosis, chronic tuberculosis of the mesenteric lymph nodes, possible tuberculous peritonitis, rickets and terminal bronchopneumonia. At autopsy the heart showed very marked enlargement. The point of origin of the aorta and pulmonary arteries, respectively, were reversed, the aorta arising in front and to the right, and the pulmonary artery behind and to the left. The foramen ovale was entirely open. The tricuspid and mitral valves were normal except for the widening of the orifices produced by the dilatation of the ventricles. There was some hypertrophy of the wall of the left ventricle, and marked dilatation of the cavity of the right ventricle without notable hypertrophy of the walls. The aortic orifice was situated, not in the left ventricle, but in the right ventricle somewhat further forward than the normal position of the pulmonary orifice. The pulmonary orifice was situated in the left ventricle in the position normally occupied by the aortic orifice. It showed marked stenosis. There was an oval opening in the ventricular septum, 5 cm. in diameter, situated in the usual position of the lesion. Dr. Dunn discussed the two forms of transposition of the great vessels, the one in which the aorta arose in front and to the right, while the pulmonary artery arose behind and to the left, but each vessel arose from its proper ventricle (so-called correct transposition) and the other form in which not only was the position of the great vessels reversed, but the aorta opened from the right ventricle, and the pulmonary artery from the left ventricle. This was called complete transposition and was the form found in the present instance. The most plausible explanation of the lesion was that of Rokitansky.

A Case of Meningococcus Meningitis in the New Born, with Interesting and Unusual Features.—Dr. J. MILTON MILLER of Atlantic City reported this case, in which the following features were of particular interest. The onset began at the age of two weeks with a conjunctivitis, mistakenly regarded as gonorrheal. A bullous eruption appeared in the second week. There followed a prolonged latent period, the symptoms of meningitis not appearing until the fourth week. The spinal fluid was of a peculiar character, gelatinizing at once upon withdrawal. This condition of xanthrochromia and massive coagulation was very uncommon in meningococcus meningitis, according to Kolmer. There were during the course of the disease ten punctures of the fontanel without apparent ill effect beyond vomiting. There were in all 260 c.c. of serum introduced without any sign of serum disease. There was an apparent improvement after the tenth injection of serum, with a subsequent return of the symptoms and death.

Accidents in Foreign Protein Administration. — Dr. CHARLES GILMORE KERLEY reported three instances in which severe reactions followed the administration of a foreign protein. The first case, a boy of 8 years, who was sensitized to rag weed, maple, golden rod, and horse serum, was under treatment with horse serum. He had been given one-half minim doses which was followed by a local reaction but by no constitutional symptoms. The dose was gradually increased at two-week intervals until four minims was given. This was followed by a violent anaphylactic reaction, from which recovery was slow but complete. The second case was that of a girl, 7 years of age, who was sensitized to wheat, oats, and barley. One day after receiving treatment she suffered a violent reaction which presumably was due to the administration of the foreign protein. The third case was that of a baby that responded to the skin scratch for milk. The administration of eight drops of Walker-Gordon milk caused a collapse. Her condition, however, was not as severe as that of the boy sensitized to horse serum. She made a good recovery.

Dr. FRITZ B. TALBOT of Boston said the sensitization to horse serum in the first case was easily explained. If we wanted to sensitize a person we repeated the injection once in two weeks; if we wished to produce immunity the injection should be given every third or fourth day. The second case that was sensitized to wheat, oats, and barley brought up the interesting question of mass reactions. Where there was a tendency to react to one of a group of foreign proteins, particularly in the vegetable world, there was also a tendency to react to the other members of that botanical group. They had found another peculiar thing. If wheat produced a reaction and one stopped giving wheat and gave barley for two weeks, the barley would produce a reaction and the wheat would not. These cases brought out the danger of treatment by serum unless one had studied the fundamental principles of anaphylaxis very carefully. The feeding of foreign proteins was safer than giving them subcutaneously.

Dr. B. RAYMOND HOOBLER of Detroit emphasized the point that after having obtained desensitization to a foreign protein a small amount of that protein must be given every day for a long period. They had been making injections per rectum in that type of cases not able to take cow's milk without developing an erythematous eruption. One might give the milk first by mouth, reducing it to very small quantity and giving it with other foods, then by gradually increasing the amount one might after three or four months produce desensitization. In this type of cases one might introduce an ounce of milk per rectum daily without trouble.

Dr. J. P. CROZER GRIFFITH of Philadelphia asked whether all reactions of this nature could be regarded as protein reactions; whether, for instance, a reaction to strawberries was a protein reaction.

Dr. FRITZ B. TALBOT replied that he thought all these reactions could be explained under the head of protein reactions. There was no proof that there was anything also that caused an anaphylactic reaction. The pure protein could be obtained from all vegetables though it was frequently present in extremely minute amounts.

Dr. GODFREY R. PISEK emphasized the point that it sometimes took a longer time to produce desensitization than had been mentioned. It sometimes took as long as six months.

Dr. DAVID M. COWIE of Ann Arbor called attention to the work of Dr. Novy, who spoke of the ability to overcome anaphylaxis by rendering the urine alkaline by the administration of potassium acetate. Dr. Novy had reported a group of cases cured by this alkaline treatment.

Dr. ALFRED FRIEDLANDER of Cincinnati said they had been following Dr. Novy's work. The cases that had received large doses of alkali showed a greatly diminished incidence of serum sickness following the use of the serum treatment.

Dr. CHARLES GILMORE KERLEY said he had treated altogether some 107 cases and had had only a few accidents. He appreciated what had been said with reference to giving the protein by way of the mouth. This route, however, was not practical when one was trying to produce immunity to horse serum. Dr. Kerley said he had reported these cases in order to demonstrate that in the matter of protein therapy and experiments with proteins our procedures should be very carefully carried out.

A Case of Appendicitis in a Nine Months' Old Baby with Autopsy Record.—Dr. ISAAC ABT of Chicago reported this case, which occurred in a child admitted to the hospital with a history of recurrent bronchitis. All the physical signs pointed to a respiratory infection. There was slight cyanosis, coated tongue, injected throat, breath sounds throughout the chest, and a few small moist râles over the left lower lobe. The heart

examination was negative, also that of the abdomen and extremities. At autopsy there was found a perforating appendicitis.

A Case of Pneumothorax in a Twelve-Year Old Boy.—Dr. ABT also reported this case. He stated that the history of the patient was entirely negative until three weeks before his admission to the hospital. Four days before admission he began to be troubled with dyspnea. Aspiration and later incision of the thoracic cavity was made. The emphysema, however, became general and the child died.

Dr. WILLIAM PALMER LUCAS asked if anyone had seen a pneumothorax in a new-born child.

Dr. J. P. SEDGWICK replied that one month ago they had a case which developed a pneumothorax on the second day after birth, for which they had been unable to assign any cause. They had had a series of *x*-ray pictures taken which showed a marked pneumothorax at first and then a gradual diminution.

Dr. DEWITT H. SHERMAN of Buffalo related the history of a case in which aspiration of the chest in empyema was followed by emphysema, and in which death resulted. The case, he said, had impressed him with the danger of aspirating the lung even when the procedure was most carefully done.

Dr. GERSTENBERGER of Cleveland brought out the point that in aspirating in emphysema it might be advisable to leave the needle in the chest for six or eight hours.

Dr. HENRY F. HELMHOLZ of Evanston, Ill., said that he had had a case somewhat similar to Dr. Abt's first case. They thought they were dealing with a lobar pneumonia on the right side. Later symptoms of peritonitis appeared and they thought this was a pneumococcus peritonitis. The child died and at autopsy they found a focus of infection in the gallbladder and an appendicitis.

Dr. J. P. CROZER GRIFFITH asked the members of the Society if they would trust the *x*-ray appearances in suspected pneumothorax.

Dr. ABT replied that the *x*-ray men said there was no doubt that pneumothorax could be diagnosed by the *x*-ray which would show the regular contour and the decidedly black areas that indicated the air-containing pulmonary cavities.

Hereditary Multiple Exostoses.—Dr. DAVID MURRAY COWIE of Ann Arbor reported this case. He said the boy, ten years of age, came under his observation as a referred case from the University Hospital. The physical examination was negative except for the multiple outgrowths and irregular thickenings of most of the bones of the skeleton. The involvement was quite definitely symmetrical. In the upper extremities the humerus, radius, and metacarpal bones showed thickening and exostoses. The carpal bones showed no deformities, ossification being incomplete and retarded. The femur showed thickening of the neck with blunt outgrowth extending downward and forward. There was thickening of the lower ends with marked spinous outgrowths projecting upward on the inner and outer aspects. The tibia showed many spines projecting downward about the head. Small spines were found projecting downward at the costochondral junction of all the ribs. The clavicles and scapulæ and the large pelvic bones were also involved. The father of the boy showed similar, larger, but not so numerous skeletal changes as those of the son. The forearms were distinctly shorter than normal, and the metacarpal bones irregular in shape and showing slight evidence of exostoses. Multiple exostoses were of two main varities, cartilaginous and fibrous. Nothing was known of the cause of this condition. Heredity seemed to be a definite factor. The disease should not be confused with myositis ossificans not infrequently seen in children.

Dr. ALFRED F. HESS of New York said he had recently seen cases very much like that of Dr. Cowie's. There were three children in one family—ten, six, and a little over two years of age—that showed this condition. The boy of ten had very decided enlargements. In the child of six the process was less well developed, and in the two-year old it was just beginning. In this instance the father had exostoses of the knees. Dr. Hess asked whether the literature showed that this condition was hereditary in the male line and whether he thought the disease had anything to do with calcium.

Dr. WILLIAM W. BUTTERWORTH of New Orleans said he had seen two cases of this kind in the same family in which the spinous processes of the long bones were affected. It was probable that the condition was not rare. French writers mentioned it and seemed to be familiar with it.

Dr. DAVID M. COWIE, in closing, said that among 220 recorded cases he had found none going back further than the father. There was no treatment that had been systematically employed. Dr. Cowie said he had made calcium estimations of the blood, but they had shown nothing in particular. As to heredity, the literature seemed to show that the disease was sometimes from the father and sometimes from the mother.

Sarcoma of the Brain Simulating Hydrocephalus.—Dr. L. EMMETT HOLT of New York reported this case. He stated that the child was admitted to the hospital at seven weeks of age with a history of having been perfectly normal at birth. The parents were healthy. They stated that they had noticed the enlargement of the head when the child was two weeks old. At seven weeks the head measured 20½ inches, while the circumference of the chest was 15 inches. The only symptom the child presented was the enlargement of the head. There was asymmetry and enlargement over the left frontal bone. At autopsy the right hemisphere of the brain was quite normal, but the left was found to be the seat of a large sarcomatous growth. The unusual feature of the case was the absence of symptoms other than those of hydrocephalus. Dr. Holt said he had never seen a similar growth in a child so early in life or one that grew with such extraordinary rapidity.

Dr. CHARLES GILMORE KERLEY related the history of a somewhat similar case in which the diagnosis of hydrocephalus was made. The child was examined by an oculist and a neurologist who could find nothing. An operation was then performed for hydrocephalus and a large sarcoma was found. This child was eight or nine months of age. It was operated on a second time and died within twenty-four hours.

Dr. GODFREY R. PISEK of New York reported this case, which occurred in an Italian baby two months and one week old. The previous history was negative, aside from a convulsion ten days before. There were no symptoms except rapid and difficult breathing and a distinct area of flatness over the right chest posteriorly with a corresponding diminution of breath sounds and a slight displacement of the heart. Pleural effusion was suspected. At aspiration six ounces of milky fluid were withdrawn. The laboratory reported that the milky fluid was sterile, composed of fat and seroglobulins. After a second aspiration the baby made a good recovery and was discharged in good condition and gaining in weight twenty-two days after its admission. This was probably the youngest case of true chylothorax on record. The etiological factor here could be assumed only and attributed to the convulsive seizure, which might have changed the pressure of the duct and caused rupture.

Dr. DEWITT H. SHERMAN of Buffalo recalled that he had reported a similar case and had exhibited the specimen of chylous effusion. In his case three aspirations were made at which 840, 260 and 1,200 c.c. respectively were withdrawn, after which the child made a good recovery.

The Treatment of Secondary Anemia in Infants by Blood Transfusion.—Dr. CHARLES GILMORE KERLEY of New York read this paper. He stated that the cases were cases of secondary anemia or of anemia and malnutrition, in all of which various food combinations and medical treatment of the anemia had been unsuccessful. The transfusions were made in the Babies' Hospital. The blood of the donor was proved fit by the absence of agglutination and hemolysis. There were eight cases in the series, and the blood examinations before and after transfusion showed the effect of the transfusion in each instance. The result in all but one of these cases was satisfactory. One case was transfused twice, and in each instance the blood examination showed an improvement, but it failed to hold longer than a few weeks. In the other cases there was no return of the anemia, and the subsequent growth was satisfactory. These children were all under two years of age.

Dr. B. RAYMOND HOOBLER of Detroit asked what method of transfusion was used, and whether more than two transfusions were given.

Dr. KERLEY said all were cases of simple secondary anemia, some were apparently anemic from birth. All showed malnutrition. The technic consisted in cleansing and cocainizing the skin over the median basilic vein of the child's arm and exposing about two inches by dissecting it free from the surrounding tissues. A small opening was made into one side of the vein with a pair of scissors and a Lindeman needle inserted. The vein below the needle was then tied off and another suture was placed over the vein and needle to hold the latter in place. A small amount of sterile salt solution was introduced to make sure that there was no leakage. A rubber tourniquet was placed on the arm of the donor, the skin cleansed over the most prominent vein and the blood withdrawn with a Record syringe until the syringe was full. This syringe was then handed to the operator working on the child and who inserted the blood into the child's vein. At the same time a fresh syringe full of the donor's blood was obtained. Each syringe was washed out with sterile salt solution before being used again to collect blood. This procedure was continued until the proper amount was transfused. One transfusion was used in each case, except the child that did not do well, and that child was transfused a second time after a thirty-day interval.

The Value of the von Pirquet Test as Controlled by Autopsy Findings.—Dr. J. H. MASON KNOX of Baltimore read this paper, which consisted in a report of the results of a study of the von Pirquet test for tuberculosis in a series of 324 infants and children, from birth to twelve years of age, in which autopsies were performed. Sixty-eight cases were found to have tuberculous lesions on postmortem examination, that was about 20 per cent. of the fatal cases examined after death. Two hundred and fifty-six, or 80 per cent., were found at postmortem examination to be free from tuberculosis. This incidence of tuberculosis in infancy and childhood agreed with Veeder's investigations, and was much smaller than that reported in European centers. It should be emphasized that no doubtful case should be called positive, but the test repeated; only those should be called positive in which there was a marked contrast between the tuberculous areas and the control site. This study seemed to furnish most reliable confirmatory evidence that among American children a properly performed negative von Pirquet test, except in extremely ill children, precluded the possibility of tuberculous infection. Of sixty-eight cases in which tuberculous lesions were found at autopsy, the von Pirquet test was made in sixty-one. In forty-five of these it resulted positively, while it was negative in sixteen. In twelve of the latter the patients were suffering from rapidly advancing widespread miliary tuberculosis, in two instances from tuberculous meningitis, and in two cases from pulmonary tuberculosis of advanced stage. It might be concluded that the tuberculin test, as described by von Pirquet, was a most reliable aid in the detection of tuberculosis in children and that a positive reaction invariably indicated a tuberculous focus, while a negative reaction established the fact that there was no tuberculous lesion except in extremely ill patients in whom the diagnosis could easily be made by physical examination.

Dr. CHARLES HUNTER DUNN of Boston said that they had made autopsies on some two or three hundred babies upon whom the von Pirquet test had been performed. Their figures were somewhat different from those just given, but this might be explained by the fact that their children were all under two years of age. The incidence in their babies had been over 90 per cent. The percentage of persistently negative reactions had been 30 per cent. Not more than one or two cases in the entire series showed a positive reaction with negative findings at autopsy. Dr. Dunn believed that the great differences in the statistical studies of different investigators could only be explained by the fact that the disease varied much in incidence and manifestations from time to time. There were periods in which one saw certain typical manifestations and a certain incidence of the von Pirquet, then a period would follow with another peculiarity in manifestation of the disease and a different incidence of the von Pirquet reactions. To get statistics of value they would have to study a million cases and cover a period of 100 years.

Dr. L. EMMETT HOLT of New York said that it had been their experience that it was very exceptional to find a positive reaction and not to find tuberculosis at autopsy. It had been said that in tuberculous meningitis it was exceptional to find a positive von Pirquet; they had found a positive von Pirquet in all cases except those that were practically moribund.

Dr. ISAAC ABT of Chicago urged the necessity of standardizing their technic and fluids and of demanding that every man should use the same fluid and technic in making his observations and that then they would have a better basis for the comparison of their results.

Dr. SAMUEL MCC. HAMILL of Philadelphia emphasized what Dr. Abt had said, and stated that it had been his experience that one got the same reaction each time if he used the same tuberculin. His experience in tuberculous meningitis was like that of Dr. Holt; he had obtained positive reactions in cases of tuberculous meningitis twenty-four hours before death.

Dr. ALFRED F. HESS related their experience with the von Pirquet tests at the Infants' Asylum. He said they gave three von Pirquet tests and three intracutaneous tests within twelve days. With these short intervals there was no danger of bringing on susceptibility. At times they got no reaction after one test, more of a reaction after the second test, and still more of a reaction after the third test. Quite a number of children that gave a negative von Pirquet reaction gave a positive intracutaneous reaction. He did not believe that one negative von Pirquet reaction meant that no anatomical tuberculosis was present.

Dr. HENRY HEIMAN called attention to an error in technique made by some. He said he had seen an arm scratched until a blood vessel was opened. That was not the von Pirquet test. The borer was the only instrument that should be used, and care should be taken not to draw blood.

Dr. J. P. SEDGWICK of Minneapolis said they had been making tests on the new born. They had been working with known antigens devised by Dr. Larson, making one von Pirquet test, then a second von Pirquet, then an intradermal test and also a complement deviation test. They had been getting about the same number of reactions with the complement deviation test as with the intradermal. This work would be reported later.

Dr. J. H. MASON KNOX, in closing, said they had used the intradermal test also and in a large series of cases the results were confirmatory of the von Pirquet tests.

The Effect on Human Milk Production of Diets Containing Various Forms and Quantities of Protein.—Dr. B. RAYMOND HOOBLER of Detroit presented this communication which he said attempted to answer the following questions: What was the minimal amount of protein that should be fed to protect maternal tissues, that was what nutritive ratio should exist between the protein on the one hand and the carbohydrate and fat on the other. Was there any difference between animal and vegetable protein in their effect on milk production? Was one kind of protein better than another to protect maternal tissues? Some twelve different diets were tested. They had found that a nutritive ratio of one to six or narrower seemed best adapted to the needs of the nursing mother. This ratio referred to the proportion of digestible protein to digestible fat and carbohydrate. They had found that animal protein was more suitable than vegetable protein in supplying nitrogen for milk and the maintenance of the nitrogen balance. The protein derived from nuts when fed with other vegetable protein was suitable for supplying milk protein and for maintaining the nitrogen balance. A diet composed exclusively of cereals, fruits, and vegetables did not supply sufficient protein for maintaining the nitrogen balance and caused a severe drain on the tissues of the mother. Of the various forms of animal protein, that derived from cow's milk seemed particularly suitable for the production of human milk protein as well as for the protection of the maternal tissues. It was found that a diet that would just maintain the nitrogen equilibrium was in many respects preferable to one which tended to add weight.

Dr. HENRY J. GERSTENBERGER of Cleveland asked how many mothers were on these diets, and whether the ages and weights of the mothers were somewhat similar He also asked how the amount of milk produced by these mothers was determined.

Dr. Isaac Abt of Chicago said he was not in a position to criticise the figures, but the matter was not as simple as it might appear. He asked what the weights, ages, and races of the mothers were, and spoke of the emotional and psychological factors that influenced the milk supply. The problem was not simply one of feeding a certain amount and kind of food and getting a definite production of milk.

Dr. David M. Cowie said it was a well-known fact that increasing the amount of meat in the dietary stimulated the milk production.

Dr. Alfred F. Hess said the fact must be taken into consideration that although animal protein produced more milk, yet the animals that produced the most protein in their milk got no animal protein in their food.

Dr. Thomas S. Southworth of New York emphasized the importance of furnishing the mother with a sufficient amount of protein to protect her body tissues. He said they had been told that the diet affected very little the production of milk. This had not been his view. It had been his experience that if the mother received a diet made up of carbohydrates with a sufficient amount of milk she would not run down during lactation, but on the other hand would have a tendency to put on flesh.

Dr. L. E. La Fetra asked Dr. Hoobler whether he had tried these mothers on other diets. Cows differed in the amount of milk they produced and it was only logical to believe that women varied in the same way.

Dr. Hoobler said that there were in all eight mothers under observation for a period of three months. A few of these mothers were on the nut diets and also on the other ten diets, so that there was had a variation of diets for these mothers. The weights of the mothers varied and the diets were not based on the per kilo body weight. The mothers all received the same amount of food. He fed them according to the calories, using about 3000. The milk was obtained by hand milking under the supervision of a nurse. The ages of the mothers were about 30 years and these were their first babies.

Luetic Nephritis in Infancy and Childhood.—Dr. William W. Butterworth of New Orleans read this paper. He stated that a search of the literature showed that apparently little recognition was given to luetic nephritis by English and American writers. German and French writers had made extensive contributions to the literature of this subject. While there was a lack of agreement in regard to the severity of the syphilitic infection and its effect upon the kidneys, upon two points there was a more complete understanding. First the clinical symptoms of nephritis in hereditary syphilis might be wanting, or so insignificant as to pass unnoticed. Second, if the child survived the early period of life, then the clinical manifestations were those commonly associated with a chronic interstitial nephritis. Cases conformed more or less to certain classifications as follows: (1) Acute parenchymatous nephritis which might be hemorrhagic. (2) Acute interstitial nephritis. (3) Chronic interstitial nephritis. (4) Myeloid degeneration. (5) Gummata of the kidney. Fetal syphilis might result in various kidney changes, such as congenital malformations, cystic kidney, and nephritis. Several observers had recently demonstrated active well-formed *Treponema pallidum* in the vascular, interstitial, and parenchymatous renal tissues. The cells when attacked by the Treponema presented a progressive phase of cell degeneration. These observations support the toxic theory, and formed a reasonable hypothesis for the complex clinical manifestations and diverse urinary findings in the kidney changes of hereditary lues. Living active *Treponema pallidum* had been found in the urine of a four months' old baby dead of congenital syphilis. The urine of congenitally syphilitic children contained a specific poison, probably an alkaloid, which when injected into animals caused death. Castaigne in 1913 called attention to a familial albuminuria dependent on hereditary syphilis. He reported twelve personal cases of albuminuria in children, occurring in four families, all having positive Wassermanns. Two of the children died of nephritis, while the other ten were apparently cured by specific medication. Judicious specific medication was curative in most of the cases. Congenital luetic nephritis was not generally recognized as having a distinct etiological basis.

Wednesday, May 30—Third Day.

The Effect of Codliver Oil in Intestinal Infantilism.—Dr. L. Emmett Holt of New York presented this paper. He stated that the subject of these observations was a girl, 8½ years of age, who was suffering from infantilism, apparently due to chronic intestinal indigestion. Metabolism observations were made at the beginning and at the end of a period during which codliver oil was administered. The metabolism at the beginning of the period showed negative balances in calcium, magnesium, phosphorus, and total ash. At the age of 8½ years the child's net weight was 27½ pounds and her height 39 inches. In nine months she gained under the administration of codliver oil 2½ inches in height and 13½ pounds in weight. At the end of the period metabolism observations showed a marked positive balance in calcium, magnesium, and total ash.

Dr. Fritz B. Talbot of Boston said that there were two points of interest in this case. One was that the negative balance could not have been present all the time, though it was probably present more than it was absent. The second point was that even with the codliver oil the absorption of available nutrition was only 66 2/3 per cent., whereas under normal conditions it was 90 per cent.

Dr. Charles Herrman of New York said this case well illustrated the point that gain in weight and increase in height did not necessarily go hand in hand.

Dr. B. Raymond Hoobler of Detroit said that the child was also fed malt, and that might possibly have something to do with the gain.

Dr. Holt said it was quite possible that the malt might have had something to do with the gain. This point was considered in the paper. Dr. Holt stated that they had confirmed the finding that in rachitic cases with the administration of calcium salts there was an increase of from 25 to 40 per cent. in the amount of calcium retained. They had thus demonstrated the value of calcium in rachitis. In regard to the negative balance, the child could not have had a negative balance all the time. There had been, however, no gain in weight for four years previous to the administration of the codliver oil. Just how much of the gain was due to the codliver oil it was hard to tell, because simply an increase in the intake of salts would cause a retention. They had concluded, however, that the oil was a large factor in the gain.

Indicanuria in Children.—Dr. H. M. McClanahan of Omaha read this paper, in which he first called attention to the paucity of the literature on this subject. The natural conclusion was that the subject was not of any importance. Indican of intestinal origin was found in the urine of children in the following conditions: constipation, chronic intestinal indigestion, duodenal and peptic ulcer, malignant growths and in all forms of acute obstruction of the bowels. Indican was produced in suppurating cavities within the body, as in empyema, pulmonary abscess, bronchiectasis, pulmonary gangrene, chronic tonsilitis, appendicitis, and in general pyemic conditions. The writer had studied the urine of 536 children, varying in age from four to twelve years, none of whom had any organic disease. Of this number 20 were hospital cases, 6 of which were suffering from empyema. All were subjected to operation. Indican was found in excess in all cases. There was one case of pulmonary abscess in which indican was constantly present. There were three cases of acute appendicitis in which indican was present, but disappeared after recovery. Indican was present in one case each of duodenal ulcer, acute ileus, and one case of pyonephrosis, in two cases of bronchopneumonia, and two cases of typhoid fever. In the 516 ambulatory cases there was a trace of indican in 97, indican was present in excess in 367, and the urine was loaded in 52. Nearly all of the group had some form of indigestion. Of the 516 cases, 337 on a reexamination showed either decrease or absence of indican and in the remaining 179 cases, indican persisted. Of the 52 cases showing excessive indican all were cases of constipation. In three cases in which indican persisted after careful dietetic and hygienic treatment

the *x*-ray showed some abnormal condition of the bowel. Many of the children were bolting their food or were permitted to eat between meals. In 11 cases in which the complete cooperation of the mothers was secured a diet was prescribed eliminating entirely meat, eggs, and milk for a period of ten days. These children received a diet solely of fruits, cereals, green vegetables, toast, bread, and butter, and were permitted to drink water freely. After this treatment and a free bowel movement daily, the urine of each child without exception showed absence of indican. Indican was present in the urine of the majority of children. A trace was probably normal. Excessive indican was evidence of either intestinal putrefaction or of some mechanical injury to the mucosa, or of some suppurative process within the body. It was frequently the result of constipation and might have an important diagnostic value.

Dr. B. Raymond Hoobler of Detroit said he thought there was some fallacy in this work. He advised using the method of decolorization with potassium chlorate, which he had found more satisfactory than taking the color of the chloroform as an index.

Dr. J. P. Sedgwick of Minneapolis asked if anyone had found as had Dr. Fleischner that the meat intake was an important factor influencing the amount of indican in the urine in older children.

Dr. McClanahan said there was no question but that the amount of meat taken influenced the amount of indican in the urine.

Clinical Observations on Poliomyelitis during the 1916 Epidemic; Prophylaxis; Description of a Characteristic Sign.—Dr. Henry Heiman of New York presented this communication, in which he said that the last epidemic had demonstrated conclusively that the poliomyelitis virus might attack any site in the entire cerebrospinal tract. In the midst of the epidemic it was comparatively easy to demonstrate certain distinct clinical types of cases, occurring about the same time, in certain localities, and presenting practically the same symptoms and signs. This seemed to indicate that there were probably a number of strains of the poliomyelitis organism, varying in virulence, and having a predilection for certain regions of the cerebrospinal tract. It was usually conceded that Flugge's droplet infection was in most cases responsible for the spread of the infection. Therefore, in order to control the spread of poliomyelitis, attention must be devoted to prophylactic measures. These were preeminently the gown, the cap, the hand brush and the disinfectants. Certain important measures had not been sufficiently emphasized. These were the wearing of a gauze mouthpiece and nose mask, or gargling of the throat and spraying of the nose, the latter to be employed before and after visiting the patient. In reference to the diagnosis certain points required emphasis. The most transient paralysis, the slightest paresis of the extremities, the faintest suspicion of rigidity of the neck, inability to flex the head (Draper's sign), the mildest muscle pain or cramps, occurring during an epidemic, should be sufficient to regard the case at least as one of potential poliomyelitis. A sign especially observed in cases of the meningeal type was a distinct tremor of the hands and fingers, a fine tremor of both hands, elicited best by having the hands outstretched and the fingers spread apart. It was present practically always in the early stage of the disease, and might persist as long as eight or ten weeks. To demonstrate this sign more clearly, it was advisable for the physician to stretch out his own fingers near those of the patient and to compare them, or to intensify them by placing a sheet of paper on the dorsal surface of the outstretched hand. The disadvantage of the sign was that it could not be used in young infants or in patients who were comatose.

A Pathogenesis of Infantile Scurvy.—Dr. Henry John Gerstenberger of Cleveland, Ohio, read this paper, in which he offered a hypothesis regarding the pathogenesis of infantile scurvy. This hypothesis was divided into four parts, of which only the first was considered to be sufficiently based upon experimental and clinical data as to permit its exit out of the domain of pure hypothesis. The writer reports a case of infantile scurvy which showed a marked reduction of the water output of the body through the kidneys without the presence of the usual and known causes for water loss via other channels, and which further showed a marked change toward a return to normal conditions after the administration of orange juice. This indicated a protective salt retention or hindered salt excretion as the cause of the transfer of a good portion of the water exeretion from the kidneys to the lungs. The same condition was present seemingly in two additional cases of infantile scurvy, as well as in scorbutic guinea pigs on an oat and water diet. It was suggested that the phenomenon observed was part of the regular picture of infantile scurvy and represented an addition to the clinical symptomatology of scurvy. A case was reported as being the counterpart to Braddon's and Cooper's polyneuritic pigeons, but had developed its symptoms on a diet of raw milk, modified by dilution with water to one-half, and by the addition of enormous amounts of carbohydrates, in the form of an infant food. The writer had confirmed the experience of other authors regarding the inefficiency of codliver oil and calcium therapy in scurvy by absolutely negative therapeutic results obtained in a case of infantile scurvy under the administration of tricalcium phosphate and codliver oil. This indicated that a deficiency of calcium in the diet or in the body played no primary rôle in the development of scurvy. There was a distinct improvement in the clinical picture of two cases of infantile scurvy upon the administration of large doses of sodium citrate. This observation suggested the possibility of the existence in the development of the clinical picture of infantile scurvy of a modus operandi similar to such as had been shown to exist in cell permeability and irritability by the researches of Jacques Loeb.

Contribution on Poliomyelitis.—Dr. Walter Lester Carr of New York presented this report on 63 cases admitted to the City Hospital during the summer of 1916, with the diagnosis of poliomyelitis. In five instances the final diagnoses were rickets, septic meningitis, enterocolitis, normal child, and staphylococcus meningitis. Of the 58 cases, seven died within eighteen hours without treatment. Of 54 cases treated intraspinously three died, a mortality of 5.5. The most frequent symptoms were irritability, hypersensitiveness, loss of appetite, and constipation. The tongue was almost always coated, sometimes tremulous. The superficial lymph nodes were enlarged in 90 per cent. of the cases, this being an early symptom. In the cerebral cases the pupils were less responsive to light than in the lower cord cases. The pulse was frequently recorded as rapid and thready; this finding was not definitely associated with temperature changes. In general there were no typical urinary findings. The highest leucocyte count was 40,000 and the lowest 9,000, with an average of 18,000. The average polymorphonuclear count was 55 per cent. There were in all 350 spinal punctures made. With few exceptions the spinal fluid was clear, with slightly or markedly increased pressure. The cell counts ranged from six to 300, with an average of 36. After intraspinous treatment the cell count invariably rose, usually above 100. Different methods of intraspinous treatment were employed, bichloride of mercury, diarsenol, adrenalin chloride, and freshly prepared immune serum. The results recorded after the use of adrenalin intraspinously were deeper and less labored respiration, improvement in the quality of pulse, increased blood pressure, usually 10 to 15 points, and the pressure of the spinal fluid on later punctures became normal. The conclusions reached after using adrenalin chloride that while not a specific, its value was unquestioned in all severe and toxic cases and those of fulminating type. The author believed that 1-1000 solution of adrenalin could be administered in doses of 1 to 3 c.c. every six to ten hours, without danger, and with better results than any other treatment that we had at present. Of this series of cases six showed marked paralysis with very little improvement; 33 showed very slight weakness of one or more groups of muscles, with daily improvement, and 12 cases showed no paralysis. The good results obtained in the City Hospital were in the opinion of the writer due to the quiet and good nursing that the patients received and to the use of immune serum and adrenalin. It was not now possible to judge conclusively of any plan of treatment.

DIGITALIS IN THE TREATMENT OF AURICULAR FIBRILLATION; AND A REPORT OF THREE CASES OF ARRHYTHMIA.*

BY HERMON C. GORDINIER, M.D.,

TROY, N. Y.

THE object of this communication is to discuss the value of digitalis in the treatment of auricular fibrillation and to record three interesting cases of arrhythmia occurring during the course of acute infectious fevers. The diagnosis of auricular fibrillation is, for the most part, comparatively simple, the gross irregularity of the ventricular action being indicated at the wrist in a decided difference between each beat as regards tension, volume, spacing, and timing, while at the heart the tumultuous irregularity of ventricular action is easily discerned with the ear or stethoscope applied to the impulse. This irregularity of the arterial pulse taken in conjunction with the presence of a definite deficit or incongruity between the rate of the clinical apex and that of the radial artery, the radial rate being much slower than that of the apex, makes the diagnosis almost positive. In cases of fibrillation coming on rather abruptly in individuals suffering with mitral stenosis, the disappearance of the characteristic crescendo type of presystolic murmur and the equally characteristic thrill, and their replacement by a murmur softer in quality and generally long drawn out occupying the entire diastole, or middiastolic in time, and unaccompanied by a thrill, are also highly suggestive, if not absolutely diagnostic, of this condition. As before mentioned, in cases of fibrillation with mitral stenosis, where the fibrillation is of short duration, as it disappears and normal auricular activity is reestablished, one is able to note by auscultation the reappearance of the previously lost presystolic murmur, and to palpate the returning strictly localized presystolic thrill. These signs are ordinarily quite sufficient to establish the diagnosis of auricular fibrillation. They may be corroborated, however, by taking short stretches of polygraphic or electro cardiographic curves, when the disappearance of auricular activity and the presence of fibrillation will be indicated by the absence of the "A" wave in the phlebo- and cardiogram and the "P" variation in the electrocardiograms, and the appearance of a true systolic venous pulse in the jugulars, and in tracings obtained from the pulsating liver, together with the presence of multiple wavelets of small amplitude in the diastolic period of tracings taken from the jugulars and apex and in the electrocardiograms. Clinical alternation is sometimes mistaken for fibrillation, inasmuch as in some cases of alternation the rhythmical irregularity in volume, so characteristic of the arterial pulse, creates waves so small in amplitude that the palpating finger fails to appreciate the difference in volume, and hence they are confused with the pulse irregularity of cases of fibrillation. Careful blood pressure observations or short strips of radial curves will dispel all doubt as to their true nature, as the radiograms in alternation show well-formed waves of large and small amplitude following each other in regular succession, the spacing between them being about equidistant, or the long time interval existing between waves of long and small amplitude rather than as in ventricular extrasystoles between the small and large waves. Blood pressure studies show in alternation a halving of the radial rate on the side of the compressed arm at the height of the systolic pressure, whereas when the pressure of the cuff is released both large and small waves pass through when the radial rate becomes the same in each wrist.

From the standpoint of prognosis and treatment the recognition of the inception of this abnormal rhythm is of great importance, for it is nearly always associated with grave changes of the myocardium, and its presence adds greatly to the load of an already overburdened heart, whose reserve is thereby made more or less limited, both by increasing its irritability and conductivity, and by impairing its contractility, and thus diminishing its tonicity. While a few subjects of auricular fibrillation whose ventricular rates are moderately slow, and whose cardiac reserve is not greatly impaired, may live fairly comfortable for months or years, the great majority in whom this rhythm is perpetual are shortlived. Ventricular rates which are maintained above 120, unless responsive to proper therapy, go on to gradual or speedy cardiac exhaustion, with great dilatation and all the concomitant symptoms of an unrelieved decompensation and death. It is probable that the immediate cause of death in many of these cases is asystole, from the sudden inception of ventricular fibrillation. In determining the prognosis in a given case of auricular fibrillation it is therefore necessary to weigh carefully the subjective and objective symptoms, as well as to have a proper appreciation of the extent of the damage to the heart muscle—as indicated by the deficit between the rate of the apex and that of the radial artery; the amount of cardiac dilatation; the change in the quality and pitch of the heart sounds; and associated valvular

*Read at the eighteenth annual meeting of the American Therapeutic Society, New York, June 1 and 2, 1917.

murmurs, as well as to the condition of the arteries and functional capacity of the kidneys, and the ability of the heart muscle to respond to active digitalis therapy.

Recognizing keenly the import of the myocardium in maintaining the circulation, and the rôle its exhausted fibers play in the production of heart failure, I would state that no form of cardiac disorder is more amenable to proper digitalis medication than the one before us for discussion. If we will pause for a moment to review the salient features of this disordered cardiac mechanism, we shall find ample justification for the above statement, for with the inception of this abnormal rhythm the coordinate auricular activity is lost and the whole ventricular myocardium is rendered more irritable from over-excitability, the result of innumerable stimuli constantly flowing from the auricles to the ventricles over His's bundle, the result of their delirious activity. This constant increased conductivity rapidly exhausts the two most important functions of the heart muscle—contractility and tonicity—resulting in a most bizarre ventricular irregularity with dilatation of their chambers and myocardial exhaustion. We have been taught by both animal experiments and clinical studies that digitalis reduces cardiac rate by vagus stimulation through its effects on the cardio-inhibitory centers in the oblongata, as this action may be prohibited by blocking the vagus impulses to the heart through the administration of atropine. It has also been known for long that this drug has a selective action directly on the muscle fibers of the heart independent of their nerve supply, improving in marked degree the functions of contractility and tonicity. In addition we know from polygraphic and electrocardiographic studies that one of the earliest effects of digitalis is to delay conductivity through the bundle of His by increasing the auriculo-ventricular interval, causing, if the action is pushed, definite heart block, which effect is especially pronounced in cases where the bundle of His and the conducting system of fibers are diseased. This action of the drug is valuable in fibrillation by reducing the number of impulses flowing from the auricles to the ventricles, thus relieving their irregularity, slowing their rate and increasing their period of diastolic rest, thereby permitting a proper filling of the ventricular chambers. It also strengthens their systolic contractions, thus relieving them of their residual blood by increasing the volume output of the ventricles, with in most instances complete relief of the general venous stasis and edema.

In laboratory animals and healthy men digitalis increases blood pressure by constricting the small arteries through vasoconstrictor influences. On diseased hearts, however, great discrepancy of opinion exists as to whether such pressure effects ever occur. Mackenzie's observations seem to show that medicinal doses of digitalis in auricular fibrillation have no effect on the musculature of the arterial walls. It seems, however, reasonable to believe, especially where fibrillation with edema and low blood pressure exists, that such results occur chiefly through its effect on improving the contractile force and tone of the heart muscle, and especially of the ventricles, thus increasing the systolic output, reducing thereby the size of the dilated chambers by relieving them of their residual blood, augmenting the aortic pressure, and permitting a better coronary arterial flow, hence improving the nutrition of the heart muscle. Its diuretic effect is not primarily renal but is doubtless due to its selective action in increasing the force and strength of the heart muscle, thus delivering to the kidneys a greater volume of arterial blood under higher pressure, relieving their venous stasis and the general edema by exciting active diuresis. Rarely do we observe marked diuresis in cases of fibrillation without edema. Clinical experience teaches that when an active standardized preparation of digitalis fails to influence for good the strength of the myocardium, no increased urinary output occurs. Because of these well-known pharmacologic actions of the drug, we have in digitalis a most valued weapon

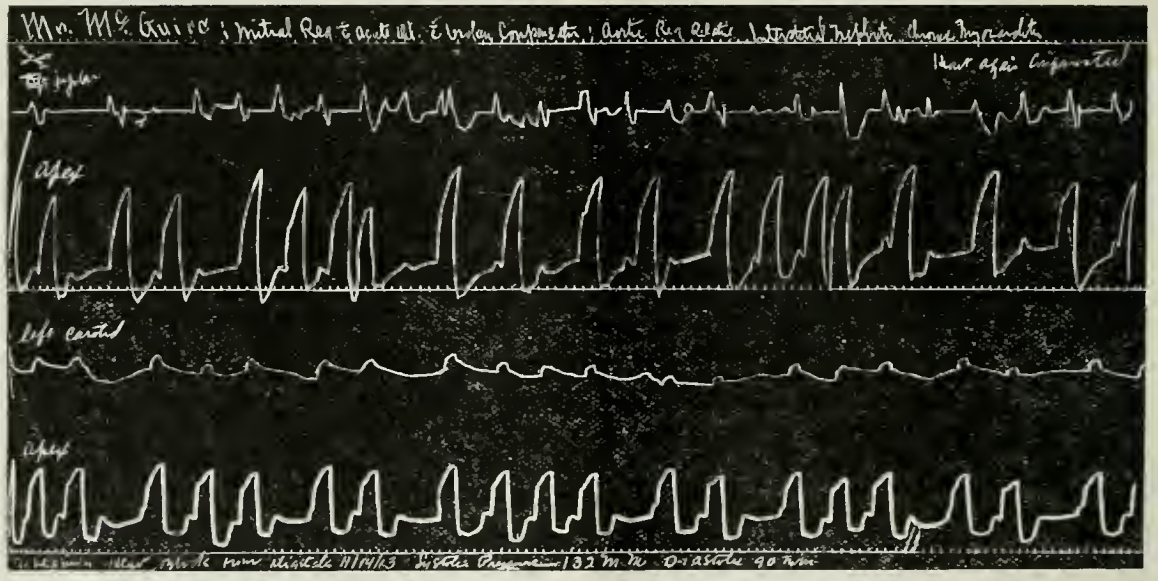

FIG. 1.—Auricular fibrillation, delayed conductivity, and occasional dropped beat due to digitalis. Note the widened A-C interval in the phlebogram and A-V interval in the cardiogram.

whereby we may relieve and prolong the lives of these unfortunate patients, so that they may live months or years with comparative comfort, often being able to work at their usual vocations. The effects from the use of digitalis or allied drugs in fibrillation are oftentimes no less than marvelous, patients in immediate peril of death being relieved as if by magic; the deficit between the rate of the cardiac impulse and radial artery gradually ceasing, the cyanosis dyspnea, and edema fast disappearing, the irregularity of rhythm and rapid rate quickly improving; and in cases of fibrillation associated with mitral stenosis the presystolic murmur long since absent, often reappearing with the improvement of the functioning of the auricles. The drug to be effectual must be used at first in doses sufficiently large to produce its definite physiological effects—*i. e.* distinct lessening of the irregularity and slowing of the pulse rate, the rate of the apex and the radial pulse gradually becoming the same. When their rates reach seventy or under per minute it is wise to discontinue the drug for a few days, carefully watching the heart rate in the interval, and if it again becomes rapid, reaching ninety or more, then to give enough digitalis to keep it at

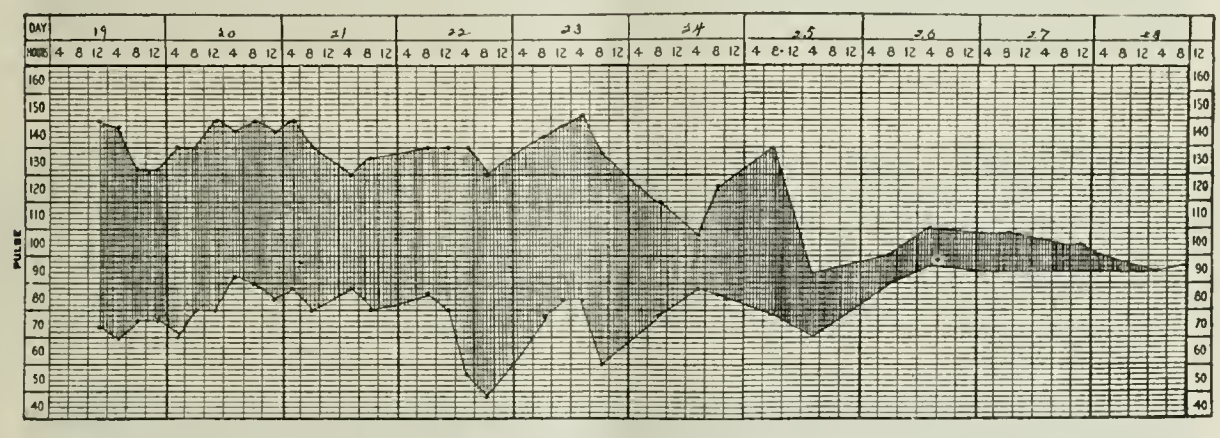

FIG. 2.—Pulse deficit chart. Record of auricular fibrillation showing marked myocardial exhaustion greatly improved by digitalis. The upper line is that of the apex rate, the lower of the radial rate; note the wide deficit at the onset and the gradual coalescence of the apex and radial rates under digitalis therapy.

about the normal rate, thus continuing the small tonic doses over long periods of time, only ceasing when the rate keeps normal and no deficit occurs between the apex beat and radial pulse, or the drug produces some toxic effect, such as nausea, vomiting, diarrhea, severe headache, marked sinus irregularity, delayed conductivity, bigemina alternation or actual heart block. No drug of this series can, in my judgment, approach at all the good effects of an active preparation of digitalis if boldly pushed until its specific cardiac action is obtained. I would like to emphasize the importance of stopping digitalis therapy in cases of fibrillation immediately on the onset of bigemina or heart block. I am satisfied that the death of the patient of one of my colleagues with aortic disease was due to the lack of such warning. It is interesting here to note that the recent observations of Dr. Canby Robinson with lethal doses of digitalis on lower animals show that the first toxic change observed was a definite bigemina, soon to be followed by ventricular fibrillation and death. It is true that occasionally certain individuals seem to possess an idiosyncrasy for the drug and can take it neither by the mouth nor subcutaneously. In such patients the drug may be used intravenously or the substitution of strophanthus, ouabin, squills, convallaria, adonis, or spartein for a time may be tried. My preference is for either a good tincture, a perfectly fresh infusion made from carefully selected leaves, or recently collected dried and compressed leaves. In endeavoring to bring prominently before you the great value of this drug in the treatment of fibrillation, I do not wish in those cases of fibrillation with edema to underrate the great good that comes from absolute rest, restricted fluid intake, Karrel and salt-free liets, and careful elimination, or in combination with digitalis, of such diuretics that act upon healthy renal epithelium as the salines, caffeine, theobromine, or theocinsodium acetate. While these drugs often work admirably in conjunction with digitalis in the renal insufficiency of pure passive congestion, increasing diuresis and sodium chloride elimination, they are ofttimes disappointing and actually harmful in pure renal dropsy, particularly where the phthalein test shows a greatly reduced functional capacity. These latter drugs should not be given in pure renal dropsy. I want also here to emphasize the fact that belladonna or atropine should never be administered in this condition, unless for some very definite reason, such as the onset of a sudden fulminating attack of pulmonary edema, as its action is to paralyze the peripheral terminaations of the vagus nerve, thus accentuating the fibrillation.

CASE I.—*Sudden Inception of Auricular Flutter During an Attack of Acute Rheumatic Fever, Transposed by Digitalis Into Continuous Bigemina and Then Normal Rhythm.*—The patient, Mrs. J. A. W., age 43 years, entered the Samaritan Hospital March 31, 1915, complaining of multiple joint pains aggravated by motion or any jar and severe sour sweats. Family history unimportant. Had measles, diphtheria, and rheumatism at 26 years of age; otherwise had been well until the onset three weeks ago of the present illness. She married at 23 years of age; has had one living child and one born dead at full term. Uses no alcoholic or other stimulants; denies venereal disease.

Present illness began three weeks ago with a severe attack of follicular tonsillitis, which confined her to bed for three weeks. Following this attack she developed pain and stiffness in her knees and wrists, which so disabled her that she sought relief by entering the hospital.

The patient is a well-nourished and developed female in the dorsal decubitus, and appears acutely ill. Both knee and wrist joints are red, swollen, and tender. The

tonsils are enlarged, crypts patulous and they look diseased. The lungs show normal vesicular breathing.

The precordial region is not prominent. No retraction or Broadbent sign is present. No palpable friction rub. Localized to region of apex is a presystolic thrill. The apex is visible and palpable in the fifth interspace from the fifth interspace to the costal border. It is not palpable because of the thick abdominal walls. The cranial nerves functionate normally. The reflexes, both superficial and deep, are normal.

The urine is dark amber, specific gravity 1022; contains small amount of albumin and a few hyaline casts. The blood shows a leucocytosis of 14,000; the blood Wassermann reaction is negative. The *x*-ray examination shows a moderate enlargement of the whole heart.

April 15, 1915.—About two weeks after the patient entered the hospital she was taken with dyspnea, rapid respirations, cyanosis, and orthopnea. The cardiac ex-

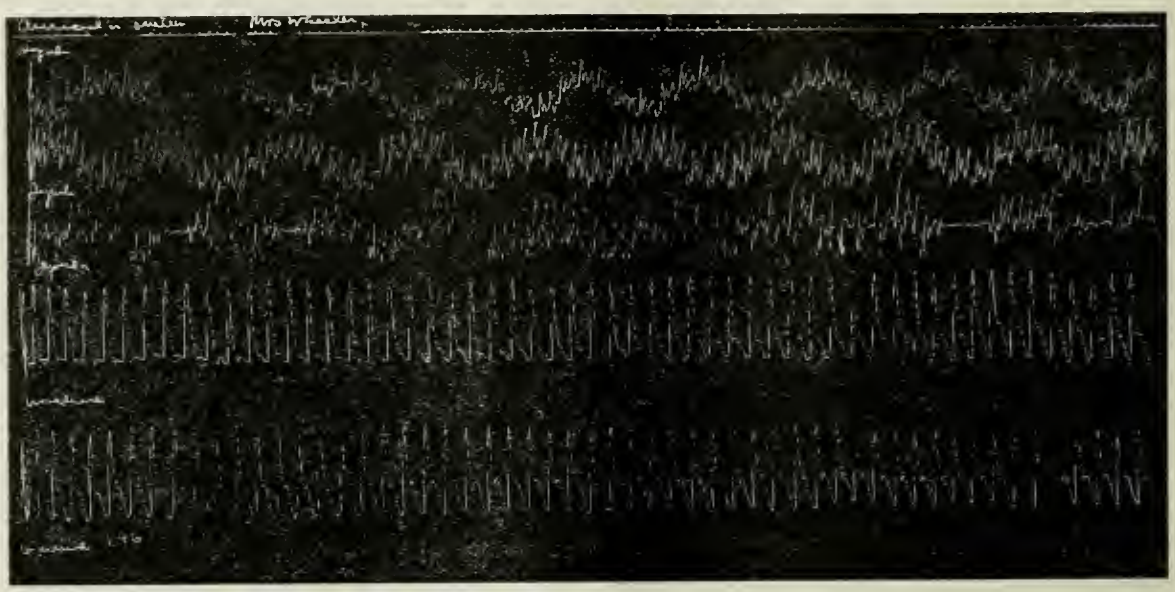

Fig. 3.—Case I. Mitral stenosis suffering with acute articular rheumatism, sudden onset of auricular flutter; radial rate, regular, 100; auricular rate, 300.

excatly intersecting the left midclavicular line. At this point and a little within is a strictly localized presystolic murmur of the crescendo type, ceasing suddenly with a slapping first sound to be followed by a systolic apical murmur, soft in quality and faintly conducted to the left. The pulmonic second sound is accentuated, but not reduplicated. No third sound or evidence of gallop exists. The radial and apex rates are 80 and perfectly regular in rhythm. Blood pressure: systolic 120, diastolic 80.

The spleen is not enlarged. Liver dullness extends amination disclosed a rapid rate, the presystolic murmur and thrill were not discernible, the ventricular and radial rates were 100 and perfectly regular, while the auricular rate was 300. Polygraphic tracings were taken which confirmed the clinical diagnosis of auricular flutter. Digitalis therapy was instituted in doses of 20 minims of the tincture thrice daily. No change was noted in the flutter for 72 hours, when we were surprised to find that the flutter had been transposed into a continuous digitalis bigemina, rather than the usual sequence of fibrillation. This finding led to the

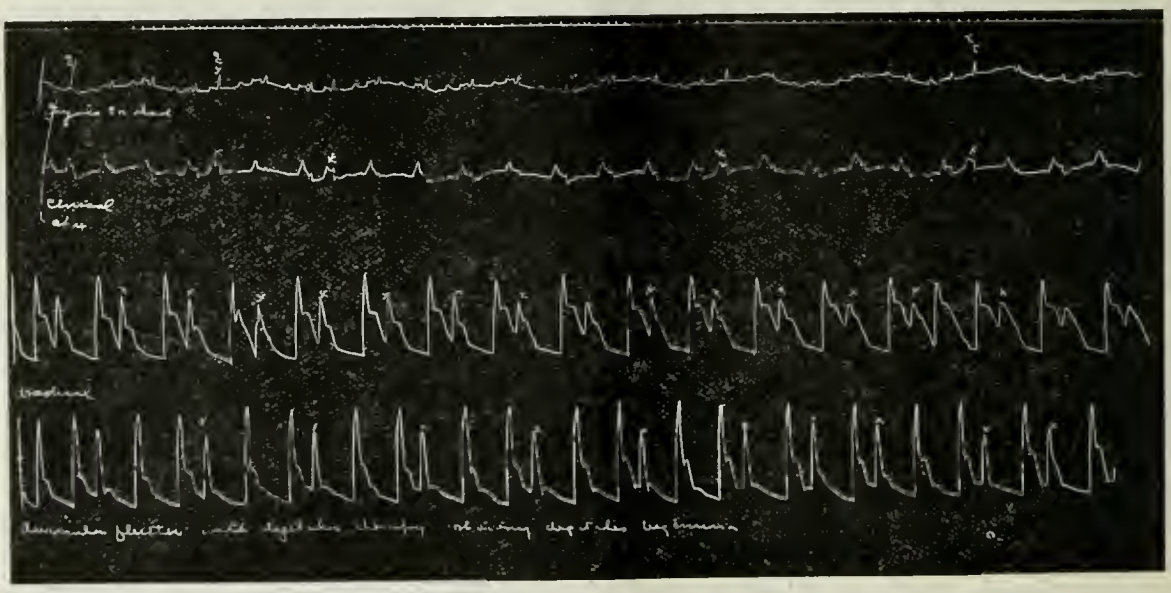

Fig. 4.—Case I. Auricular flutter transformed into digitalis bigemina under digitalis therapy for seventy-two hours.

discontinuance of the digitalis. A few days later the normal rhythm was again restored with a regular pulse both at apex and wrist at 70, with at the same time the return of the presystolic murmur and thrill. The patient remained in the hospital until June 1, 1915, and had no recurrence of the arrhythmia.

Case II.—*Sudden Onset of Auricular Fibrillation During an Attack of Grippe.*—Mrs. D., æt. 37 years, married. Entered the Samaritan Hospital April 2, 1917, complaining of pains all over—headache, distressing unproductive cough, and sore throat. She was nauseated and had recurring chilly sensations.

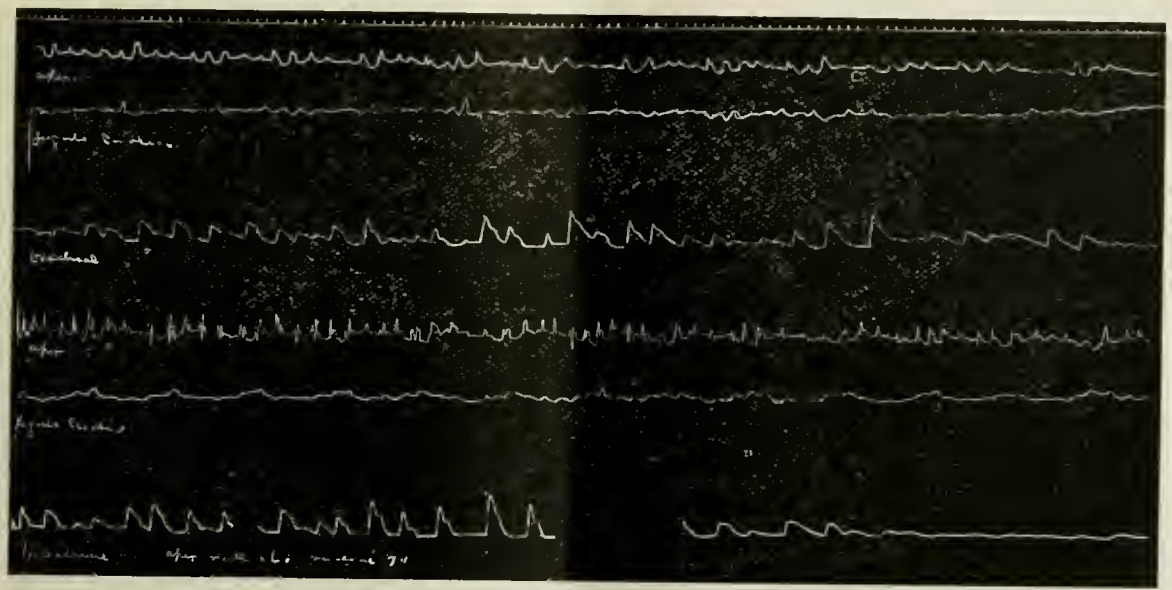

Fig. 5.—Case II. Auricular fibrillation occurring during an attack of grippe. Note the gross pulse irregularity and absent auricular wave in the cardiogram and phlebogram.

Father died at 87 years of age of heart disease; mother died at 72 years of age of apoplexy; otherwise the family history is negative.

The patient had chorea at 12 years of age; pleurisy at 20 years of age. Four years ago she had quinsy. Otherwise she has always been healthy, save dyspnea on exertion. She has had three healthy children and two miscarriages. Denies venereal disease. She uses no alcoholics or drugs. She sleeps well; has a good appetite and the bowels are regular. She menstruates rather profusely. She had no knowledge that her heart was diseased.

Examination shows the patient to be poorly nourished, spare, and under-developed. Her expression is anxious. She is supported by three pillows. The skin and mucous surfaces are very pale. There is no edema or cyanosis. The respirations are quickened. The radial pulse rate is 80, and it is quite regular. A presystolic murmur and thrill are present. No deficit exists. The mucous surface of the throat is injected, tonsil enlarged, no exudate present. Dry and moist rales are heard throughout the lungs; otherwise chest is normal. The liver dullness extends from the fifth rib to costal margin; lower border smooth, not painful and not pulsatile.

Red blood count, 4,800,000; white blood count, 19,000; neutrophiles, 87 per cent.; eosinophiles, 1 per cent.; lymphocytes, 10 per cent.; transitional, 2 per cent.; hemoglobin, 85 per cent. The urine is dark amber, acid, specific gravity 1,024, clear, albumin positive, sugar negative, red blood cells, hyaline and fine granular casts. Blood cultures show no growth on agar or bouillon in 48 hours.

On April 5, three days after admission and while her acute febrile symptoms were present, she suddenly appeared much worse; became distinctly cyanosed, had labored breathing, and complained of palpitation. She slept poorly. Examination disclosed an irregular pulse

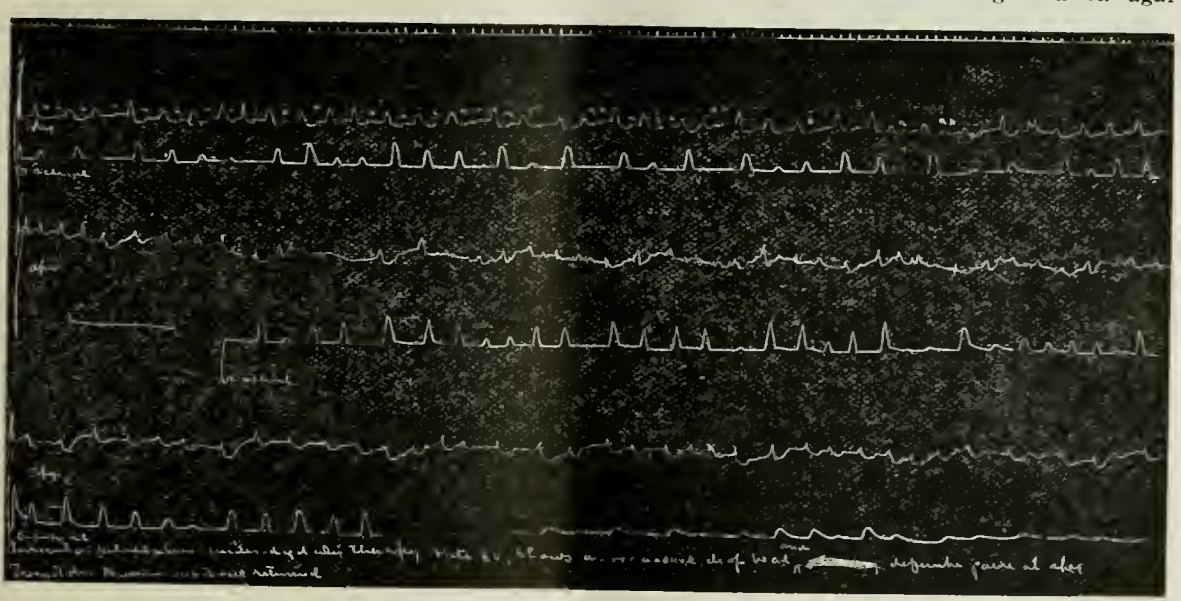

Fig. 6.—Same case as shown in Fig. 5 under digitalis medication. Note the recurrence of the auricular wavelets in the cardiogram, the widening of the A-V interval, the occasional occurrence of dropped beats—"2 to 1 heart block." The presystolic murmur and thrill have returned.

at 86 per minute, of feeble strength and volume, time, and spacing. The impulse was diffuse, apparently strong, irregular in force, and rapid, its rate being 158 per minute. The heart action was tumultuous and irregular; the presystolic murmur and thrill had disappeared. The jugulars stood out in bold relief and presented a large systolic venous movement. There was, as illustrated by the accompanying chart, a distinct pulse deficit. The cardiac dullness as outlined by percussion, showed the right border 4 cm. from the midsternal line and the left 13 cm. The upper border was at the lower border of the third rib. The polygraph showed the gross irregularity of the radial pulse, the large systolic venous movement with absence of the "A" waves both in the phlebo- and cardiogram. In all leads of the electrocardiogram the "P" waves were absent and fibrillating wavelets were present. She was given 20 minims of tr. digitalis every four hours, and after four days marked changes for the better were noted. Subjectively she was relieved of her dyspnea or air hunger, cyanosis, and insomnia; the urinary output was increased. The cardiac rate was slowed, the apex and radial rates fast approaching each other. The pulse was stronger, less irregular, and of greater volume. On the sixth day of digitalis medication the lost presystolic murmur and thrill reappeared, and tracings taken at that time showed in many cycles of the phlebo- and cardiograms returned "A" waves, with at the same time distinct diminution of conductivity with the occasional dropping out of beats; the latter also being appreciated on auscultation over the apex impulse.

She has gone on for a period of four weeks without the slightest discomfort, with practically no deficit between the apex and radial rate, and with a pulse of about 70 per minute, though still irregular. The presystolic murmur and thrill have remained and no edema has developed.

It seems probable that this case of acute fibrillation was induced through toxic changes of the heart muscles occasioned by the grippe infection, resulting in sudden dilatation with acute myocardial exhaustion. The good effect of rest and digitalis is noteworthy.

CASE III.—*Recurring Syncopal Attacks Probably Due to Cerebral Anemia Occurring Toward the Close of the Convalescent Period of a Case of Severe Typhoid Fever, the Result of Auricular Flutter.*—Mr. John Y., æt. 35 years, entered the Samaritan Hospital Jan. 28, 1917, in a delirious state, complaining at lucid intervals of severe headache, pain in the abdomen, and great weakness.

He was well nourished, without edema, his skin was hot and dry, pulse quickened but regular, tongue fissured, dry, and brown and sordes had collected on his gums, lips, and teeth. He talked incoherently, was disorientated and very stupid.

At the base of the right lung the physical signs of consolidation existed; elsewhere harsh but fair vesicular breathing was elicited.

The cardiac dullness was normal, sounds clear but distant, rhythm normal, rate 90. Blood pressure, systolic 120, diastolic 90.

Liver dullness extended from the fifth interspace to two centimeters below the costal border in the right mamillary line; the lower border was smooth and not tender.

The spleen was palpable 2 cm. below the costal margin; it was definitely tender to the touch. The abdomen was universally tympanitic and distended; it was tender in the right lower quadrant. Rose spots were abundant on the abdomen and chest.

The pupils were mid-wide, equal, responsive to light and accommodation, the discs are normal. The patella and tendo-Achillis jerks were lively. The umbilical reflex was absent. The bladder and rectum were not controlled.

The urine was cloudy; specific gravity 1022; albumin in definite amount present; no sugar, leucocytes, erythrocytes, or bladder epithelium present; numerous motile organisms were seen. The Widal agglutination test was positive; the Wassermann reaction negative. The red cell count was 3,250,000; the white cell count 5,200; hemoglobin 60 per cent.

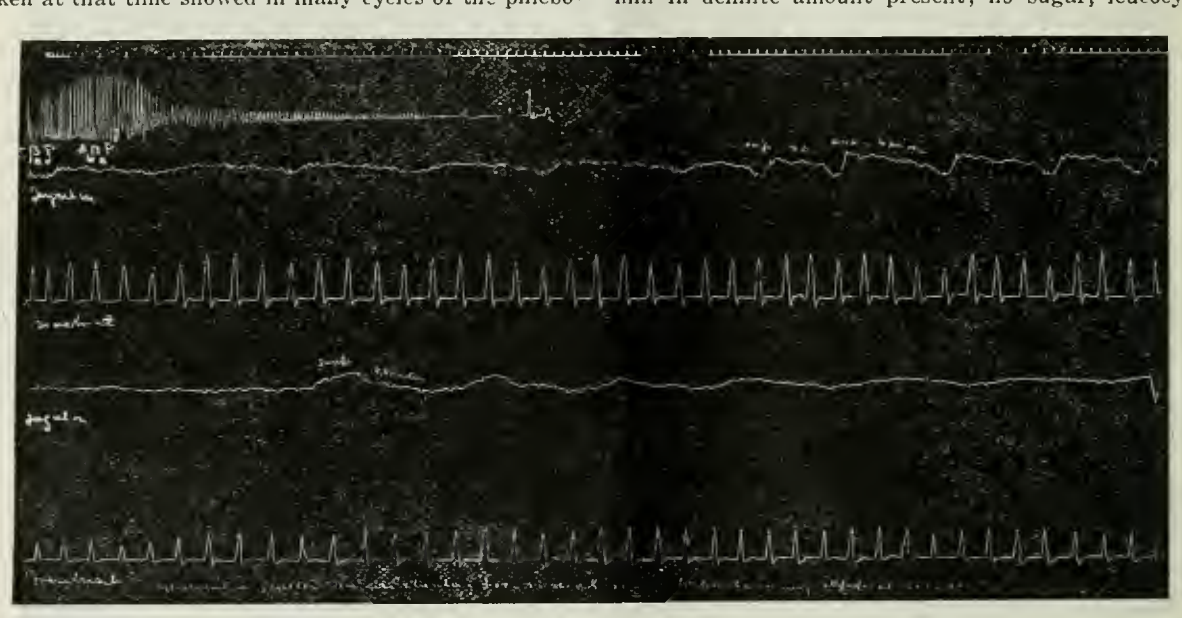

FIG. 7.—Case III. Auricular flutter occurring suddenly during convalescence from a very severe attack of typhoid fever. Auricular rate 300, radial rate 100. Normal rhythm was restored in five days with digitalis.

The patient's temperature ranged for a period of about six weeks from 102° to 104°. During the third week of the disease he had three large intestinal hemorrhages which nearly cost him his life, but they were controlled, and though his condition was desperate for days he gradually improved. At the beginning of the seventh week he developed a sharp attack of facial erysipelas which was easily controlled with ichthyol. A few days later his temperature and pulse fell to the normal, his mind became clear, he appreciated his surroundings, and his appetite became ravenous. He was much emaciated, having lost thirty pounds in weight.

Suddenly while in recumbency he was taken with a faint attack, became very pale, the pupils were widely dilated, and his eyes were turned upward and outward under the cover of the upper lid. He was absolutely unconscious, but had neither muscular twitchings nor convulsions. The attack lasted about five minutes. When he returned to consciousness he was bewildered and disoriented, his pulse was rapid but regular, respirations quickened, and he was quite cyanosed. He

had five attacks of a similar character during one week. I saw him in his last attack which was exactly similar to the one above described. His pulse was regular, feeble in volume, easily compressed, with the rate of 100; his jugulars were pulsating very rapidly, a series of fluttering wavelets which with a stop watch were counted at about 300 per minute. Polygraphic tracings were immediately taken which showed an auricular rate of 300, with regular rhythmic ventricular responses of 100 per minute, "3 to 1 heart block." His systolic blood pressure was 100 mm.Hg.; the diastolic 60. He was given 20 minims of tr. digitalis thrice daily for 6 days, when the normal rhythm was reestablished.

Three weeks later he was discharged, having had in the interim no return of the flutter.

89 Fourth Street.

COMPROMISING WITH CONSUMPTIVES.*

By JOHN B. HAWES, 3d, M.D.,

BOSTON.

DIRECTOR, TUBERCULOSIS CLINIC, MASSACHUSETTS GENERAL HOSPITAL; SECRETARY, MASSACHUSETTS STATE TUBERCULOSIS COMMISSION.

I have written this paper because I feel that what has always been a difficult problem to me may be a source of difficulty to others, and that its frank discussion may lead to its solution. The question in brief is this: What is consumption? What does this word mean, both in diagnosis and treatment? Have we any definite, set, minimum standards or requirements that must be met before we can say that this or that patient is a consumptive and must be treated as such?

When I was in the medical school some fifteen or sixteen years ago the diagnosis of pulmonary tuberculosis rested largely on the finding of bacilli in the sputum; in their absence the signs in the lungs had to be very plain and distinct, including dullness, bronchial breathing, rales, etc., before a positive diagnosis was considered. At present we seem to be requiring less and less on which to base a diagnosis. In Massachusetts, with the establishment of local tuberculosis dispensaries in every town or city of 10,000 inhabitants or over, this problem is becoming acute. Physicians are in charge of these clinics whose business it is to discover cases of consumption. The result is that many cases are diagnosed as such on what I personally believe to be insufficient evidence.

Some physicians still demand the presence of bacilli in the sputum before making a positive diagnosis. Others demand definite signs in the lungs before so doing; while still others attach more value to the history and constitutional signs and symptoms than to signs in the chest. The result is chaos, as far as any definite fixed standards are concerned.

With the possible exception of syphilis, I know of no other subject of equal importance concerning the diagnosis and treatment of which there seems to be so much confusion and disagreement. In Massachusetts, for instance, one of our very best men, a strong believer in the value of percussion, has said that "interscapular dullness plus some constitutional signs," justifies a tentative diagnois of tuberculosis in childhood. Another physician of equally high standing justified his diagnosis of tuberculosis in a certain child on the ground of exposure from a grandmother and because the child lived in a notoriously crowded and unhealthy neighborhood. The two largest clinics in Boston, one devoted entirely to tuberculosis and the other, the Massachusetts General Hospital where I do my own work, are at great variance as to what constitutes tuberculosis.

Again, what do we mean by the words "treated as such" that I used above? To one group of physicians, prominent among whom I might name Dr. Joseph H. Pratt of Boston, adequate and proper treatment means home treatment. To others, and I place myself in this group, home treatment alone is not adequate and proper treatment. We believe that sanatorium treatment, for a while at least, is essential for the average patient's welfare. Dr. Pratt and others apparently are of the opinion that our sanatoria are but a waste of money, while I, having been intimately connected with their management in Massachusetts during the past ten years, naturally have a different opinion. And so I might go on indefinitely.

I do not believe that any one point of view either in diagnosis or treatment will prove to be entirely correct. Each one of us must be willing to give way and if necessary to compromise with what he believes to be the ideal course, or else little progress will be made. I do not like to compromise, nor do I like halfway measures of any kind. On the other hand, half a loaf is better than none, and it is better for a patient to do something that is right, even if it falls far short of the ideal, than to do nothing at all. It is all very well for the physician to demand complete evidence before making his diagnosis, and having made it, demand that every consumptive do something radical, give up his work, break up his family, and go to a sanatorium or elsewhere, but in many cases the physician must be content with less than this or else he will accomplish little.

So far as individuals are concerned, the "no compromise" attitude, in my own case at least, would mean that as soon as I had made a definite diagnosis I should advise every patient to give up everything and to go away to a sanatorium at once. This would be quite regardless of necessary sacrifices, such as breaking up the family, giving up work, and providing funds. Perhaps if we all assumed this attitude we might cure or arrest a few more consumptives than we are now doing. I doubt very much if the good we would accomplish, however, in this way, would offset the harm we would do in other ways. The following are a few striking cases in point:

Case 1.—A. Z., a Lithuanian of 29, married, with one small child, came to see me with a history of a sudden and fairly profuse hemorrhage. Family and previous history were absolutely negative. He was a strong finely built man looking the picture of health. Physical examination showed what appeared to be a typical tuberculous process at the right apex with dullness, slight alteration of breath and voice sounds, and rales. Aside from this I could find nothing abnormal. The blood, urine, temperature, and pulse were normal, while the sputum showed no tubercle bacilli, but many organisms inside and outside the cells resembling those of influenza. Here was enough evidence to justify a diagnosis of incipient pulmonary tuberculosis and to treat the patient as such which would have meant making him give up his work and as soon as possible go to a sanatorium. Nevertheless, I felt that this case would bear watching. I saw this man again two

*Read at the annual meeting of the American Climatological and Clinical Association, May 29, 1917.

weeks later and found the process at the right apex apparently clearing up. At a still later visit it had practically disappeared nor had there been any more blood. As before, the patient felt perfectly well and under my observation has continued so.

Here a compromise seemed justified as to both diagnosis and treatment. It would have been very easy to have stamped this man as a consumptive and to have entirely upset his life, for the time being at least. While I do not feel that this is altogether a safe course to advise general practitioners and students to pursue in that a hemorrhage with signs at one apex is usually enough on which to make a positive diagnosis, I am glad that in this instance I acted as I did.

Case 2.—I. L. This patient was a Hebrew of 33, married, who had just started out in business for himself. He had a very early tuberculous process first called to notice by a hemorrhage. His physical condition was excellent, but he was much depressed and worried. I doubt if I could have persuaded him to go to a sanatorium at first even had I advised it. Instead of doing this, however, I did my best to encourage him and cheer him up. I allowed him to keep general supervision over his store, but made him shorten his hours and report to me at frequent intervals. He finally of his own accord decided to quit work for a while and go away for a rest. He is steadily improving and has recently gone back to work.

Here the diagnosis of tuberculosis was never in doubt. So far, however, events have justified me in not making this man give up everything in order to go to a sanatorium. Time alone will show whether or not I have advised him wisely. Were he of a lower grade of intelligence or were there any constitutional signs or symptoms, I should undoubtedly have acted differently.

Case 3.—N. B. D. This patient, an intelligent man of 35, married, with two children and in comfortable circumstances, consulted me in June, 1916. My diagnosis at that time was incipient phthisis, although the sputum was repeatedly negative. There were a slightly elevated pulse and temperature and a few definite and persistent rales at the right apex. He lived outside the city with every facility for outdoor sleeping and proper hygiene. His work was not hard. I told him that I should place him on trial for a month and if at the end of that time he were not better he must take more radical measures. I have seen him every month up to the present, during which time he has steadily improved, and has gained in weight from 148 to over 160 lbs. In January, 1917, he caught cold and his sputum became positive for the first time, while the moisture at the right apex increased. I have talked with absolute frankness to this man and know that he understands the situation perfectly and fully realizes the chances he is taking. He has recently and entirely of his own accord gone to Saranac to stay as long as necessary.

An older physician, and one of the most eminent in the State, has seen this patient in consultation and fully approves of the course I have pursued. Indeed, he told me that he would consider it a calamity if he were made to break up his home and go away. On the other hand, I should consider it a greater calamity if he were to break down and in addition infect his children while under my care. This is a border-line case, and one concerning which I am frankly in doubt. Were he single and unattached, I should certainly have advised him to go to Saranac or elsewhere at once, but I am sure that he would not have gone; as things have turned out, this is very satisfactorily settled.

Case 4.—M. L. This patient, an unmarried woman of 45, had taught in a large public school for many years. She had had many burdens to bear outside of her school work and had carried a heavy load of financial worry and responsibility. Despite this she felt very well and consulted her physician more on account of her friends' wishes than for her own sake. Examination showed what was probably a chronic tuberculous process at both apices, dullness, altered voice and breath sounds, and, occasionally, a few dry squeaks. The scanty amount of sputum she was able to raise was negative. She had no cough. Temperature and pulse taken over a considerable period of time at home were normal. The patient herself except for being rather tired felt perfectly well. I found this a difficult problem. The local physician who had sent her to me did not like to take the responsibility of allowing her to continue her work. I took the matter up with the local health board. It was finally decided first, that the case was not to be officially reported, as this would at once make it necessary for her to give up her work, and second, that she was to report regularly every month to me and that the minute any active signs developed such as cough, sputum, etc., or as soon as I considered her in any way a danger to the children, she must give up teaching. This was made clear to the patient and to all concerned. So far she has done very well. Recently she has obtained leave of absence for a month and is going away, somewhat against her will, for a vacation which she has not had for five years. My last examination recently made shows the same signs in the lungs, a negative sputum, and excellent general condition. She plans to resume her work in the fall, providing I allow her to do so.

I do not doubt but that there are many physicians who consider the course I have followed in this instance to be radically wrong. Indeed, ten years ago I frankly admit I should have thought so myself. At present, however, I believe it to be a justifiable one, both from the point of view of the patient, who has sufficient intelligence to understand the situation thoroughly and to cooperate in every way, as well as in regard to the children, whom I do not consider to be running any risk.

Case 5.—G. H. This patient, a married woman of 42, consulted me in September, 1915. There was a history of profuse hemmorrhage of two or three cups of blood the previous May, following which she took a fairly strict outdoor rest treatment for a few months. Sputum had been repeatedly negative. Over the upper two-thirds of the left lung there was some dullness, with numerous rales and dry squeaks. Temperature and pulse were normal. My provisional diagnosis was tuberculosis, but I was unwilling to send this patient away or to do anything more radical than to make her lead a sensible quiet life at home. There were no children. I have seen her at regular intervals up to the present time. Always the sputum has been negative while the process in the lungs is steadily clearing up. The general condition has been excellent during this entire period. I have finally come to the conclusion that this is not a case of tuberculosis but rather one of apical bronchiectasis.

As things have turned out, I feel very glad now that I did not send this patient away to a sanatorium. Physically, such a course would have done no harm and possibly some good. From the social and mental standpoint, however, I am sure that it would have done harm if she had been definitely stamped as a consumptive.

Case 6.—Peter P., a wealthy young Italian, was referred to me in September, 1916, with a positive diagnosis of pulmonary tuberculosis and a positive sputum, both of which facts he himself knew. The signs in the lungs were slight, and the general physical condition was very good. He was extremely depressed and worried, however, so much so that were it not for an older brother of whom he was very fond he would have

preferred to do nothing at all for his health, and would have rather welcomed an early death. Three or four years previous, he had been excessively alcoholic; in addition, a neglected luetic infection had affected the central nervous system, causing various distressing symptoms. Although this man certainly knows that he has tuberculosis, and except for going to a sanatorium is living a sensible proper life in every way, I have never in his presence used the words "tuberculosis" or "consumption" at any time and do not intend to do so. It has seemed to me that he has enough to combat as it is without adding to his burdens. At present he is in California, where he went ostensibly on a business trip. As a matter of fact, it is more for health than business that he has gone, and of this he is perfectly aware. Dr. George Evans of San Francisco in a recent letter states that this patient came to him for a moderate hemorrhage. When he returns I shall be interested in finding out what course will be best to pursue under these circumstances.

CASE 7.—J. D. This patient is a married man of 45 and a clerk for many years in an office where the hours are favorable and where he works under the best hygienic conditions. He was referred to me because he had been refused life insurance on the ground that he was below normal weight, and because of certain suspicious signs in the lungs. He felt practically the same at the time of my examination as he had been feeling for many years. I found a chronic and very inactive process in the lungs with a positive sputum. I explained the situation in detail and told him that I would put him on trial and that providing he would see me once a month and would abide by my decision he need not give up his work or take any radical steps at present. I examined his wife whom I found to be strong and healthy. There were no children. The man for whom he worked willingly allowed him to come to the office an hour later and to leave an hour earlier than usual. So far he has done very well, and is gaining in weight and strength.

Here, again, there are doubtless many who would differ radically from me in the course I have advised in this instance. If the disease had shown any signs of activity in the way of temperature and pulse, and, indeed, if he had been younger, I should certainly have made him give up his work and devote his entire attention to his health. Again, were he financially differently situated I should likewise have advised his giving up everything. I believe that the course I have advised, however, is the best one in this individual case, but I am quite ready at any time to change my ideas should events prove that I am wrong.

Recently I was asked to prepare some definitions and minimum diagnostic standards for cases of tuberculosis with negative sputum for the purpose of the Framingham experiment. I found this a most difficult task. The final draft as accepted by the committee is as follows:

DEFINITIONS.

1. "Loss of weight." By loss of weight should be understood an explained loss of at least 5 per cent. below normal limits for that particular individual within four months' time.

2. "Loss of strength." By loss of strength in its pathological sense is meant an ease of tire which is unusual for that individual patient and which cannot be satisfactorily explained.

3. "Fever." An occasional temperature of 99° should not be considered fever. A temperature which persistently runs over 99° when taken at least four times a day over a period of one week should be considered of significance and to constitute fever.

4. "Elevation of pulse." Where the average normal pulse of the patient is already known, an elevation of 15 beats per minute when the pulse is taken quietly at home during various periods of the day should be considered abnormal. In cases where the average pulse is not known, and, of course this constitutes the majority of cases, we should consider an average pulse of 85 or over in men and 90 or over in women to be abnormal. The combination of a subnormal temperature and an elevated pulse as defined here should be considered of great importance.

5. "Hemorrhage." Any amount of blood, with or without sputum, requires medical investigation as to its course. Blood streaks, blood spots, etc., may or may not mean tuberculosis. On the other hand, a hemorrhage of one or two teaspoonfuls is presumptive evidence of the disease.

6. "Family History." An occasional case of tuberculosis in the patient's uncles, aunts, cousins, etc., should not be considered of importance. It is an important fact when the patient's immediate relatives, such as father, mother, or grandparents have been tuberculous.

7. "Exposure." Childhood exposure, no matter how slight, is of the greatest importance. Moderate exposure among normal, healthy adults of cleanly habits is of less importance. Of course, prolonged contact with unhygienic habits or surroundings may be a dangerous factor at any age.

8. "Cough." No cough is characteristic of tuberculosis. A persistent cough for six weeks requires investigation. Tuberculosis can exist without any cough whatsoever.

9. "Sputum." The presence of sputum is not necessary for a positive diagnosis. Constant sputum, with or without cough, requires investigation. A positive sputum following one or several laboratory examinations is not to be required for positive diagnosis.

10. "Hoarseness." Any hoarseness or a persistent "huskiness" requires investigation.

On a basis of these definitions the following minimum standards in the diagnosis of active tuberculosis have been formulated:

11. When the constitutional signs and symptoms and definite past history are absent or nearly so, there should be demanded definite signs in the lungs, including persistent rales at one or both apices. By "persistent" it is meant that the rales must be present after cough at two or more examinations, and that the patient must be under observation at least a month.

12. In the presence of constitutional signs and symptoms such as loss of weight and strength, etc., as defined above, there should be demanded some abnormality in the lungs, but not necessarily rales.

13. A process at the apices should be considered tuberculous, and a process at the base to be non-tuberculous until the contrary is proved.

14. A hemorrhage as defined above is evidence of active pulmonary tuberculosis until the contrary is proved.

15. One should consider a typical pleurisy with effusion as presumptive evidence of tuberculosis. One should not consider a dry pleurisy as conclusive evidence of active tuberculosis without other signs and symptoms.

16. Pain in the chest and shoulders, night sweats, digestive disorders, etc., may be present, and should be investigated.

17. In every doubtful case one should demand that the patient should be kept under observation for at least one month with repeated sputum examinations before making a definite diagnosis.

It remains to be seen whether or not these diagnostic standards will prove satisfactory for the Framingham experiment and for general purposes. At all events it is undoubtedly true that there must be many cases similar to the ones I have cited above, that are exceptions to these rules and in which compromises are necessary and justifiable.

29 Gloucester Street.

THE PATHOLOGICAL PHYSIOLOGY OF THE HEART AS REVEALED BY THE POLYGRAPH AND THE ELECTROCARDIOGRAPH.*

By LOUIS FAUGERES BISHOP, A.M., M.D.,

NEW YORK.

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK CITY; PHYSICIAN TO THE LINCOLN HOSPITAL.

We all bow in admiration to the master minds of medicine who by ordinary signs and records have interpreted many diseases and processes and built up a very complete system of diagnosis. Accurate observation, both in the laboratory and the ward must be intensively cultivated.

But it happens that many events in the circulation in well and sick people cannot be detected by the unaided senses. Consequently, the introduction of instrumental methods has contributed a vast sum of knowledge in a most important field of practice. Hence, a meeting of the Section on Pathology and Physiology would be incomplete indeed at the present time if it did not at least illustrate and enumerate the achievements of this new science, which was opened for the first time to the profession at large, but not to laboratory workers, by the publication of Mackenzie's great work on the heart in 1908.

I remember very distinctly the satisfaction of understanding, in a measure, for the first time, after reading Mackenzie on the nature of the condition then known as "nodal rhythm," and now known as auricular fibrillation; then the gradual elucidation of one irregularity after another through the past decade, as the Mackenzie polygraph, and later the electrocardiograph, furnished the definite records on which to classify cases.

In this science of abnormal myocardial function, the physicist, physiologist, and the pathologist, meet in close cooperation. The physicist supplies us with the instruments and teaches us the laws that govern the mechanical activities; the physiologist points out the healthful action of the organ, and the pathologist its disorders.

There is no more remarkable example of the application of physics to medicine than the electrocardiograph. This instrument is a string galvanometer, and a good brief description is found in Lewis' "Clinical Electrocardiography." He describes it nearly as follows: The instrument which is described is known as a "string galvanometer," the invention of Einthoven, a Dutch physiologist. It consists essentially of a powerful electromagnet, the poles of which are closely approximated; and of an extremely delicate conducting fiber of silvered quartz or glass which is stretched in the narrow gap between the two magnetic poles. If minute currents are led through this fiber as it lies in the magnetic field, the fiber moves in response to the tested current in a plain at right angles to the lines of magnetic force across the gap. The magnified shadow of the fiber is vertical, and is projected by means of an optical system and powerful light onto the horizontal slit of a camera; the shadow moves at right angles to and across the slit, and the movements are photographed on a sensitive film which travels behind the slit. The galvanometer is now made in New York City, and is a very serviceable instrument.

In practice, an electrode is attached to the right arm, the left arm, and the left leg of the patient, and a record is made of the three combinations that are possible in such an arrangement, namely: from the right arm to the left arm; from the right arm to the left leg; and from the left arm to the left leg. These are known respectively as Leads I, II and III.

The other instrument, which I am able to bring with me and show you, has contributed perhaps more to the knowledge of irregularities even than the electrocardiograph because of its wider distribution in use, and is known as the Mackenzie ink polygraph. To illustrate its universal applicability I show you over 2,500 tracings taken in actual clinical work. The movements due to the circulation are conveyed by means of a tube containing air, and registered by a tambour on which the lever rests.

The excursions of the lever are recorded on a moving strip of paper by pens moistened in ink. Of course, the instrument contains a clockwork arrangement for moving the paper, a time marker which marks dots at intervals of one-fifth of a second, and a special arrangement for getting the radial pulse. The instrument when once adjusted to the wrist and to the neck gives a simultaneous record of the wave motions in radial artery and jugular vein, and the observations can be continued as long as desired, which is very valuable when the heart only misbehaves once in a while and we want to know what the nature of the disorder is.

The pathological physiology of the heart, as revealed by the polygraph and electrocardiograph, has been classified into seven particular types of disorder. These types, as is true of all diseases, often merge one into the other, and two may be present at the same time. They are: (1) Sinus arrhythmia, (2) heart block, (3) premature contractions, (4) simple paroxysmal tachycardia, (5) auricular flutter, (6) auricular fibrillation, (7) alternation of the pulse.

Had this been a clinical meeting, it would have been a simple matter in this great city to have had examples of all these disorders before you.

Sinus arrhythmia is chiefly important because it is not of serious importance, and occurs as a

*Read before the Section of Pathology and Physiology at the Sixty-Eighth Annual Session of the American Medical Association, New York, June, 1917.

physiological phenomenon in young children. It can be reproduced at any time in comparatively young people by taking a long breath. It consists of a difference in the length of the interval between the beats. When exaggerated in children it has sometimes led to the suspicion of myocarditis, and the children have been treated as invalids when they should have been playing out of doors. That can no longer happen under the advice of those who understand the use and interpretation of the polygraph.

The impulse of the heart ordinarily begins in the auricle and is transmitted later to the ventricle, so we have the auricle and ventricle contracting in rhythmic succession. If disease destroys the muscular contiguity or conductivity, we have the auricle and ventricle out of relation to each other. This has received the name of heart block, and is beautifully shown by the instrument described above, and it is due to this instrument that our knowledge of this condition exists.

In many people suffering from disturbed metabolism we find the heart apparently missing an occasional beat. The fact is, however, that the heart is not, as a rule, missing a beat, but the beat is occurring prematurely, and may pass unnoticed, while the succeeding beat is very large, and emphasizes the length of the quiet interval. This is called premature contraction.

When for any reason the heart abruptly becomes very rapid for a period and suddenly ceases to be rapid, we say that the person is suffering from paroxysmal tachycardia. This has been a most difficult field of investigation, and is still the ground of many disputed points. However, our instruments have disproved many previously held beliefs and pointed out not a few new facts.

One of the most recently recognized conditions is the extremely rapid though regular auricle, usually 250 to 300 per minute. It is always revealed by the electrocardiograph and occasionally by the polygraph.

The knowledge of auricular fibrillation is one of the most important contributions of clinical medicine that has come from the student of pathological physiology. In this condition there is a trembling palsy of the auricle, which transmits a vast number of impulses to the ventricle, and the ventricle becomes very rapid and irregular. It is the disease that yields most strikingly to the use of digitalis.

Alternation of the heart can be detected in many instances only by the polygraph. It is of extreme importance because it is a striking evidence of failure of the heart muscle. It consists of an alternation in the size of the beats.

These seven varieties of disorders of the heart beat have been worked out by the use of these instruments and found the groundwork of our analysis of living pathological hearts. It is indeed a most beautiful and interesting study, and I should be most happy to have any of the members of the association visit my cardiac laboratory at any time during the meeting and take part in the use of these instruments and examine the records.

Treatment of Erysipelas.—Chlumsky gets the best results from a mixture of phenol, camphor, and alcohol with quinine inwardly.—*El Siglo Médico.*

PRACTICAL POINTS IN THE USE OF STROPHANTHUS.*

By EDWARD E. CORNWALL, M.D., F.A.C.P.,

BROOKLYN, N. Y.

The rise of strophanthus in the general esteem of the medical profession was slow until recent years, when the introduction of strophanthin made it easy to demonstrate its extraordinary power as a heart stimulant. Boos says of strophanthin: "It is the one active principle of the digitalis group which approximates most closely in its action to the effects of the combined digitalis bodies as they occur in the leaves."

The preparations of strophanthus which need be considered are the tincture and strophanthin. The tincture was once said to be unreliable, and most writers on strophanthus have repeated the assertion; and more recently it has been stated as a partial explanation of this alleged unreliability, that the active principles are changed in the alimentary tract so that they lose part of their efficacy. This assertion has not received confirmation in the author's clinical experience of many years with this preparation. If unsatisfactory results have been obtained with the tincture, a possible explanation may lie in the fact that it is generally given in too large doses. There seems to be no reason for believing that the tincture of strophanthus is less reliable than the tincture of digitalis, or other vegetable tinctures.

Strophanthin is defined in the Pharmacopeia as a mixture of glucosides derived from *Strophanthus kombé.* As offered by reliable drug houses it is derived from that and other varieties of strophanthus. The strophanthin derived from *Strophanthus gratus* is said to be identical with the exceedingly toxic ouabain, and has a different dosage from that of the *Kombé;* and these facts, as Satterthwaite has pointed out, make caution advisable in its use.

The dosage of the tincture which has been found most effective by the author is much smaller than that recommended by most of the textbooks and drug catalogues, which give the average dose at about 8 minims, (range 3 to 15 minims). The author's regular dosage is from one and a half to 3 minims, given every four hours. The regular dosage of strophanthin, as the author uses it, ranges from 1 1000 grain to 1/250 grain, given every four hours or less often. These doses of the strophanthin made by a well-known manufacturing drug firm, whose product is the one most used by the author at the present time correspond to doses of the tincture of ¾ minim and 3 minims respectively, according to the statement of the manufacturers. Under certain conditions strophanthin may be given in larger doses, even as large as 1/100 grain, but such large doses should not be repeated oftener than once in twenty-four hours; and doses of 1/250 grain should not be continued for long at the four hours interval, except in extreme cases.

The dose of strophanthin as given in the Pharmacopeia is 1 200 grain. The dose of Merck's strophanthin is stated to be from 1/320 grain to 1/60 grain. The dose of the Thomas-Merck strophanthin, which is made from *Strophanthus gratus,*

*Read at the eighteenth annual meeting of the American Therapeutic Society, New York City, June 2, 1917.

is stated to be from 1/20 grain to 2/5 grain. The dose of the strophanthin of Burroughs, Welcome & Company is stated to be from 1/500 grain to 1/100 grain, the average dose being 1/200 grain. These doses are given for comparison with those mentioned in the preceding paragraph, which are the ones found most effective, as well as safe, by the author.

The tincture of strophanthus should be administered by mouth, well diluted with water. Stropahanthin is best given hypodermically, sublingually or intravenously. The intravenous method is theoretically the best for quick effect, but is not always convenient, and requires strict precautions in its employment, for it possesses a certain amount of danger. The hypodermic method is generally to be recommended, because it combines effectiveness with convenience and safety, and is within the capacity of the nurse to carry out. The objection of Boos, that hypodermic administration of strophanthin "causes most intense pain and disturbance," is not borne out by the author's experience; at least, he has received few complaints from patients of pain, although not infrequently local irritation was complained of which, however, was usually slight. One patient, who received not less than three hypodermic injections of strophanthin daily during the past eleven months, has not shown any local disturbance or felt more than a tingling sensation from some of the injections. By injecting deeply the local irritation can be minimized. The sublingual method, in which a hypodermic tablet is placed under the tongue, dissolved, and absorbed, is a convenient one which does away with the hypodermic technique.

An idiosyncrasy in regard to the effects of strophanthus is sometimes observed when the drug is taken by mouth, and this manifests itself by nausea, anorexia, or, most frequently, by diarrhea. This idiosyncrasy is not observed often enough to make it necessary to consider these gastrointestinal symptoms as regular effects of the drug. In a case where the tincture given by mouth produced them, and where strophanthin given sublingually also produced them in slight degree, these symptoms were not observed by the author when strophanthin was given hypodermically.

The general indications for the use of strophanthus are those of a direct heart stimulant. In any cases where the systolic output requires to be increased, this drug may be used. In this field it competes with digitalis, and, in the author's experience, has been found to have a wider range of applicability than digitalis. While in some cases of cardiac insufficiency, particularly those occurring in young adults with a comparatively healthy myocardium, digitalis may prove the more effective, the author has found strophanthus the more effective in all types of heart disease in children requiring a direct stimulant; also in mitral stenosis, in aortic incompetence, and in all cases where myocardial degeneration, acute or chronic, are present in notable degree. He has on many occasions given the two drugs for alternating periods of several days, and questioned the patient or nurse regarding the comparative results, and almost invariably the testimony has been in favor of strophanthus. Even in lost compensation from mitral incompetence in chronic valvular disease of inflammatory origin, which is considered the ideal field for the exhibition of the power of digitalis, the author has found strophanthus so effective and so free from unpleasant effects, administered in his preferred doses, that he has come to use it in that condition more or less regularly.

The contraindications to the use of strophanthus are not numerous. It is contraindicated in those cases where rest alone is sufficient to restore compensation. The gastrointestinal idiosyncrasy is a contraindication to its use by mouth, but not to the hypodermic administration of strophanthin. And it should not be given immediately after a strong course of digitalis.

Compare with these contraindications those of digitalis, viz.: ability of the heart to recover compensation by rest alone; childhood and old age; the existence of much myocardial degeneration, acute or chronic; acute endocarditis; mitral stenosis and usually aortic incompetence; atheromatous arteries; most conditions with high blood pressure; gastrointestinal irritation produced by its ingestion; its tendency to produce cumulative toxic effects; and its tendency to produce heart block.

On the other hand, strophanthus compares favorably with digitalis in the fact that it has few contraindications, and in the extent of its therapeutic range, and in that it has a special advantage in its freedom from cumulation.

Following are some accounts of the use of strophanthus in particular conditions, as the author has learned to use it.

In acute endocarditis and other acute inflammations of the heart with decompensation extensive enough to call for heart stimulation, tincture of strophanthus is given, usually in doses of two minims every four hours. In a child of three or four years, the usual dose is one-half minim and in older children, a minim or a minim and a half. In some forms of acute myocardial inflammation, notably diphtheretic myocarditis, the myocardium responds sluggishly to any heart stimulant, and the doses given may be a little larger than those mentioned above. It is considered undesirable to give direct heart stimulants in cases of acute inflammation of the heart, but when there is definite and progressive cardiac insufficiency, they are required just as in other cases of cardiac insufficiency.

In typhoid fever with notable signs of myocardial degeneration, tincture of strophanthus is given in doses of two and a half minims every four hours. In cases of acute cardiac failure strophanthin is given in good-sized doses. The author has seen remarkable improvement follow the hypodermic injection of 1/500 grain of strophanthin in a suddenly developed dilatation of the heart in a typhoid patient, who had walked around with his disease for two weeks. This dose was continued every four hours for a few days, and then tincture of strophanthus was substituted in the doses above mentioned. The patient remained in bed for three months and made a good recovery.

In the author's plan of heart stimulation in pneumonia, strophanthus occupies the chief place. Ordinarily it is given in small or moderate doses, one and a half, two, two and a half, or, exceptionally, three minims of the tincture every four hours; and

usually combined with strychnine sulphate in doses of one-sixtieth to one-thirtieth of a grain, every four hours. In extreme cases of myocardial failure, or in suddenly developed ones, strophanthin is given hypodermically, in doses of 1/500 grain, every four hours, or in a single dose of 1/100 grain or less. In an extreme case of cardiac failure, with a rapid and almost imperceptible pulse and extensive pulmonary edema, occurring in the fifth day of pneumonia, and apparently brought on by the fact that the patient got out of bed in delirium, the author has seen the hypodermic injection of 1 100 grain of strophanthin followed promptly by recovery of the heart to such an extent that the urgent symptoms cleared up, and the patient was able to go on to defervescence, which took place two days later. A physician of forty, who had shown symptoms of chronic myocardial degeneration for six months previous, developed pneumonia which extended over both left lobes, and in which the invading pneumococcus was identified as of type I (Cole's classification). The heart stimulation given throughout the active period of the disease consisted of strophanthin, 1/1000 grain, given hypodermically every four hours, with strychnine sulphate, 1/60 grain. On the eleventh day the patient defervesced by lysis.

In chronic valvular disease with decompensation of considerable degree, requiring direct heart stimulation, strophanthus tincture is given in doses of two or three minims every four hours, or strophanthin, 1/1000 grain, hypodermically, every four hours. In extreme decompensation in mitral stenosis, with auricular fibrillation, strophanthin is given hypodermically, every four hours, in doses of 1/500 grain, or even 1/250 grain, and usually morphine sulphate in combination with it in doses sufficient to alleviate the dyspnea and restlessness. This combination of strophanthin and morphine has given the author the best results which he has been able to obtain in this class of cases. After securing compensation, which is often fragile, it may be necessary to keep up the administration of strophanthus in reduced doses, and sometimes of the morphine also.

In conditions of chronic myocardial degeneration with loss of compensation, strophanthus is employed when strychnine is not sufficient. Ambulant cases are given one or two minims of the tincture every four hours, and cases confined to bed, one to three minims every four hours. In the severe cases strophanthin is given alone or with morphine, in the manner before described. The superiority of strophanthus over digitalis nowhere appears more clearly than in the treatment of advanced chronic myocardial degeneration.

In conclusion, the author desires to emphasize this point in the use of strophanthus: that it should be used in the right doses, which, except when used for emergencies, or after establishment of tolerance, seem to be much smaller than those which have been generally recommended; for it is only by using it in the right doses that the best results can be obtained. There is reason to suspect that when given in excessive doses, especially if long continued, it can injure the heart, perhaps more than digitalis does.

SOME SUGGESTIONS REGARDING THE URETHRITIS PATIENT.

By WALTER S. REYNOLDS, M.D.,
NEW YORK.

In the treatment of urethritis I have been impressed with the fact that while great attention is paid to the application of medicinal measures other matters of scarcely less importance are not infrequently apt to be neglected. Little details which to the physician may seem trivial, or so simple as to require no detailed explanation, are not infrequently matters with which the patient has had no experience. He may endeavor to use his best judgment in the matter, but, lacking experience or knowledge, he is liable to error or mistake which may more or less seriously retard recovery or interfere with treatment. To bring these matters to attention and to offer some suggestions regarding diagnosis is the object of this paper.

One of the most striking illustrations of the necessity of fully instructing patients came under my observation several years ago. It made a lasting impression on me, and taught me the necessity of going fully into details with patients on any matter regarding treatment which it may be necessary for them to carry out. A young woman came to my office in great haste and anxiety. She had been ordered by her physician to use as a douche a mild solution of carbolic acid. No directions had been given as to the manner in which the solution was to be prepared, and, without giving the matter any consideration, she had poured the required amount of strong carbolic acid into the douche bag, and then, adding the water, proceeded to use the douche. The result may be imagined.

Preliminary to a consideration of the necessary instructions to the patient with urethritis, a few words regarding diagnosis may not be out of place, for on a correct diagnosis depends much of our successful management of the case.

The importance of a complete history should not be underestimated. This is much more important in chronic urethritis cases than I believe is generally supposed, for the history thus obtained not only frequently aids in the diagnosis but may also be of much assistance in formulating a suitable line of treatment. It may also aid in determining the cause of the urethritis. In acute urethritis a profuse purulent discharge does not necessarily imply a gonococcic infection, and in the less acute or chronic stages, stricture, with or without alcoholic or sexual excesses, prostatitis, stone, and papilloma are only a few of the causes which may be suspected by careful history taking.

Microscopical examination of the discharge seems hardly necessary to mention, and yet how often is it neglected. Routine examination affords much valuable information, especially in the acute stages of the disease. These, together with the urinary examinations and the symptoms of the patient, give us much information as to the progress of the disease and the effect of treatment. It must be remembered, when noting the appearance of the urine, that the interval of time since the previous urination must be taken into account in making comparison with a previous specimen, or erroneous conclusions may be drawn.

In chronic cases, urethroscopic examinations are of the utmost importance. A correct understanding of the cause of the trouble can seldom be appreciated without it, and treatment which does not take into consideration this fact is likely to prove disappointing and to lead many to the conclusion that chronic urethritis is an incurable disease.

One other point in connection with the diagnosis deserves mention: that is the inspection of the parts. A patient's word is poor evidence as to the condition. He is well meaning, but untrustworthy, in this respect. As many things may be seen by the trained observer that escape the patient's attention, the only reliable evidence is that which we see ourselves. The physician should never be satisfied with being told that there is a discharge; he should know the character, amount, and length of time it has been allowed to accumulate before observation. To illustrate the necessity of careful inspection, I shall refer to an experience which I recently had in visiting a clinic in this city. A patient presented himself with a profuse purulent discharge. The assistant whose duty it was to examine the patient, a young man not without some considerable experience in the work, noted the presence of the discharge but failed to see that it was coming from beneath a somewhat phimotic prepuce and not from the urethra. In such conditions a cleansing of the preputial opening and an examination of the meatus and the urine will serve to reveal the source of the pus.

One of the first considerations in the treatment of urethritis is cleanliness. This includes not only such measures as washing and cleansing the parts, but also those of proper dressings to keep the parts as free as possible from discharge. This applies more particularly to the acute cases, where the discharge is more profuse than in the chronic cases. It is not at all infrequent to see men who are careful regarding the regularity of their bath negligent regarding the condition of the preputial cavity. Under such circumstances it requires only slight causes to set up a balanitis or balanoposthitis, a complication not infrequent in urethritis where cleanliness is neglected. When the preputial opening is small, the difficulty of keeping the parts clean is greater than when the prepuce can be freely retracted. In such cases a syringe can be used to wash out the preputial cavity and lessen the chances of infection. This is far better than to be obliged to incise the foreskin and incur the possibility of infecting the wound.

I have seen all sorts of dressings which patients have used for the purpose of cleanliness, even to no dressing at all, which, aside from the filthiness, certainly fulfills one of the objects of any dressing, which is the removal of the discharge. The best form of dressing, which in my opinion fulfills all the requirements, is that of the square of gauze with a hole in the center large enough to slip easily over the glans penis. This allows free drainage, is easily applied, and when replaced sufficiently often keeps the parts fairly clean, and is certainly much better than any bag and cotton arrangement or wad of cotton stuck in the preputial opening, both of which tend to dam the discharge back in the urethra rather than allow its escape. If the square of gauze is used, the patient should be warned, as he should be in any case, against allowing the prepuce to remain retracted back of the glans with the liability to the production of an irreducible paraphymosis.

Whatever form of dressing is used, it is important that directions be given for its destruction and the care of the hands after removing the dressing. It would hardly seem necessary to refer to this, but the negligence and carelessness of some patients, no matter how intelligent, is sometimes astonishing.

Regulation of diet may not be considered of very great importance or deserving serious attention, and directions are often given in only a perfunctory way. But when we consider that the composition of the urinary secretion depends to a large extent upon the diet, and that the urine must be passed over a mucous membrane already inflamed by the invasion of some pathogenic organism, it can be readily seen that the question of diet must play an important role in the treatment of the disease. Indeed, errors of diet may in some instances be directly responsible for an attack of urethritis, or for the lighting up of an old trouble. Such cases have not infrequently come under my observation. Specific instructions should be clearly given as to what articles of diet may be allowed. Directions to eat plain and simple food may be sufficiently understood by the person giving the directions, but may be interpreted in various ways by different people. In this, as in every other disease, each individual's taste and constitutional peculiarities have to be considered in the matter of diet, for "what's one man's meat may be another man's poison." For instance, milk, ordinarily a simple and easily digested food, may for some be a highly indigestible food.

Regulation of the diet should also have regard to the proper regulation of the bowels. Too great restriction may interfere with regularity of bowel movement, a matter of greatest importance. It may be necessary to resort to cathartics, but if this can be avoided by judicious regulation of the diet it is, in my opinion, far better. In some instances, injudicious catharsis has resulted in epididymitis. While considering the subject of diet we must direct attention to the necessity of maintaining an abundant urinary secretion. This is to be accomplished, of course, by the use of water in sufficient amount to secure the desired result. Individuals differ greatly in the activity of the kidney function, and the amount of water required to keep the urine in the desired condition must differ in each case. The administration of water serves two purposes: it insures frequent washing out of the urethra in the best possible way, and also serves to render the urine bland and non-irritating. As it is impossible to say how much water may be necessary, I have found it best to direct that sufficient be drunk to keep the color of the urine a pale straw color. A point of some practical importance is the time at which the water is to be drunk. If it is used freely in the late afternoon or evening it may interfere with sleep by the frequent calls to empty the bladder. I have sometimes seen this mistaken for a sign of involvement of the posterior urethra, and it is best, therefore, to order that water be freely taken in the morning, and in smaller amounts

later in the day. Patients seldom fail to take medicines regularly as directed, but the directions regarding the use of water often require frequent repetition, and constant observation of the urine. Plain water may be distasteful to some patients, in which case a lithia tablet added to the water, or the use of very weak tea, may overcome the difficulty.

What restrictions with regard to exercise are we to place on the patient with urethritis? In the acute stage, of course, it is a more important consideration than in the chronic stage of the disease, though even then a certain amount of restriction is necessary. I am firmly of the opinion that if patients in the acute stage were confined to bed better results could often be obtained. This is, however, seldom possible, so we are generally obliged to content ourselves with such restrictions as may be possible under the circumstances, and to prohibit those activities which would be manifestly harmful, and yet allow the individual to pursue his usual avocation. The manual laborer can, of course, seldom observe the injunctions which might be placed on a man in some other line of work, but all can be impressed with the necessity of care and the importance of avoiding any extra or unnecessary activity.

In the treatment of urethritis, injections are usually employed at some time during the course of the disease. All sorts of syringes, good, bad, and indifferent, are sold, usually on the recommendation of the druggist, who knows nothing of the requirements of the particular individual to whom they are sold. A cheap syringe is seldom to be advised. A make of syringe which I have found in every way satisfactory is not obtainable at the present time on account of the war. This particular syringe came in several different styles, so that a proper tip could be selected for the needs of the patient. The piston worked freely and smoothly, and did not allow the fluid to leak backward as it does so frequently in the cheaper kinds. It is to be hoped that our American manufacturers will supply us with a similar model, though I know of none on the market at present.

The selection of a syringe is a matter of no little importance, and must be decided according to the necessities and requirements of the individual patient. The kind of syringe best adapted for the man whose meatus is small may be entirely unfit for one of the opposite sort. Whether a syringe with a soft rubber tip meets the indications better than one of a different kind can be decided only by the observation of the physician. One of the objections to the soft rubber tip is the difficulty of cleansing it.

When it has been decided what sort of syringe is best adapted for the patient's use he should be given definite instructions as to its proper employment. It seems a very simple thing to inject a solution into the urethra, and yet I have found that few patients know how to use a syringe properly.

Cleanliness, gentleness, and thoroughness are essentials to the proper use of hand injections. The syringe is to be kept clean by washing; the solution, by pouring a sufficient quantity to fill the syringe into a small glass, and then filling the syringe. To insure urethral cleansing the patient should urinate before using the injection.

Too much emphasis cannot be laid on gentleness in urethral medication. Not only is the selection of a proper syringe most essential to this, but the manner in which the injection is used is important. My method is to direct that the solution be used at about body temperature. The syringe is filled, and held in the right hand, while the penis is held by the other hand at such an angle to the body that the penoscrotal curve of the urethra is straightened, the penis being at the same time drawn somewhat out so as to obliterate as far as possible the folds of the urethral mucous membrane. The tip of the syringe is now firmly held at the meatus and the solution slowly and gently injected, only a sufficient quantity being used to distend the urethra comfortably. If it is desired to hold the solution in the urethra, the fingers grasp the meatal opening as the syringe is removed and compress it the required length of time.

A suspensory or jockstrap is often advisable, and at times a necessity, for the man with urethritis. Men with varicocele, which perhaps ordinarily may give no trouble, are particularly liable to epididymitis during an attack of urethritis, and in such cases a support is always advisable. The suspensory is, I believe, generally preferable to the jockstrap. A suspensory, to be serviceable, should be properly fitted, otherwise it may do more harm than good. I have seen cases where an ill-fitting suspensory was responsible for the development of epididymitis. The physician should be prepared to advise some particular make which can be depended on to meet the requirements. He should also see that it is properly adjusted so that the scrotum is well supported, but without undue constriction of any part.

The wearing of a suspensory after definite indications for its use have ceased to exist is not to be commended. There are some men who after having a support for a short time feel that it is impossible to do without it, and continue to wear it as a matter of habit. It is always well to tell a man, when advising the use of a suspensory, that it is a temporary expedient, which is to be discontinued as soon as possible. Where it is necessary to continue the use of a support for any length of time those made of silk are much more comfortable, especially in the summer, than the heavier cotton ones.

In this paper I have endeavored to bring forward some of the things which, after a considerable experience in the treatment of this disease, I believe are worthy of more consideration and attention than they sometimes receive, and to suggest rather than to advise particular ways or methods regarding them, realizing that individuals and not methods must be considered in dealing with them.

THE TIME ELEMENT IN SOME PHYSICAL PROCESSES.

By J. A. HAGEMANN, M.D.,

PITTSBURGH, PA.

OTORHINO-LARYNGOLOGIST TO THE PITTSBURGH HOSPITAL.

WHATEVER qualifying definition of the vocable "time" one may adopt in other associations, the term, when relevant to the physician's province, signifies the relative sequence of events in the history of some abnormal physical state. It is familiar that an apparently protracted series of experiences may occur in a dream that chronologically is but momentary. Sometimes persons who have been under only brief minor anesthesia relate that they endured apparently long protracted distress, quite at variance with their transitory stupefaction. Drug habitues will in fancy tread the columned corridors of their nebular palaces for days, nor feel the pangs of hunger or thirst. In reality it is but a "dope-dream" of brief duration. To them time may fly as with the wings of Mercury or trudge with leaden heels. Some people, when ill, even in the absence of delirium, have defective conception of the passing of days. Patients will insist that they "never slept a wink last night," whereas a trustworthy nurse will report that many hours were spent in slumber. So time is a more or less relative term from an invalid's viewpoint.

Merely casual observation would probably leave one under the impression that chemical reactions are but variations of an expeditious process, of which the quickly effervescing Seidlitz powder is an exponent example. In reality there are chemical processes whose completion demands long periods of time; sometimes months, even years. To the physician the chronology of spontaneous biochemical processes must ever prove of singular interest, for by the designed promotion or retardation of the same he may hope to effect therapeutic results which nature in the present status of its routine attains only inadequately. When an individual contracts diphtheria, a variable period of incubation intervenes before the noxious toxins begin to be produced and intromitted into the blood and lymph currents. If the victim of such invasion be possessed within himself of sufficient antitoxin to counteract the baneful effects of the toxins, or if, within his economy, the antitoxin be produced in proper amplitude for maintenance of equilibration, the prospect is propitious. In a large percentage of cases, however, this happy equipoise does not prevail. The toxins are usually generated so rapidly that the patient is likely to succumb before the thwarting antitoxin can be autogenetically produced in adequate copiousness. In this extremity an antitoxin borrowed from a previously and designedly inoculated animal is introduced, and forthwith the neutralization of the toxins begins and goes on apace. Granted an adequate period of time, the individual himself would probably propagate the requisite units of antitoxin. Redoubled acceleration of this often tardy function would then effect the same result as the prevalent use of equine antidiphtheria serum.

Early in the last century Berzelius directed attention to the circumstance that in a great number of cases the mere presence of a third substance induces an inordinate acceleration of a chemical reaction, although apparently not itself participating reactively therein. This third substance can be recovered unchanged upon completion of the reaction. He called this process catalysis. Platinum is the most familiar catalyser, and the manner in which it expedites certain chemical processes borders on the marvelous. It was soon discovered that catalysts are present in living cells, in which alliance they are referred to as enzymes or ferments, but their intrinsic character is still obscure. It is, however, known that such catalytic agents, while exercising their functions, in the human economy, take great precedence in time over any confirmatory experiments performed in the laboratory, even under the most propitious circumstances. Manifestly, then, an elusive third element participates in physiological processes that evince variable degrees of celerity, and consequently is a dominant hastening or temporizing factor.

Arrhenius formulated the theory that electrolytes are substances which, in solution, are separated into electrically charged ions. It turns out that with all electrolytes disassociation increases progressively with a rise in temperature. In general physiology this law of Arrhenius applies to vital processes in animals and plans just as it does in test tubes. The slow rate of the heart beat in cold blooded animals and the feverish celerity of the same in warm blooded ones suffering from some pathological condition are equally subject to this law.

It is conceivable that accelerating the production of antigens, and thereby retarding the multiplication of the invading hosts, regardless of so-called antisepsis, by increasing the activity of languid, yet endowed defensive entities, would be a judicious procedure. Or, if this prove unavailing, the institution of measures to militate against the fecundity of the infective organism. The latter method is pursued advantageously when ice is applied over an infected area. In order to "gain time" for the production of an army of phagocytes, we chill the invaders, which are notably more vulnerable to the benumbing influence of a low temperature than are the body's inherent defenders. Similarly, an acceleration of the healing process of fractured bones would be a desideratum. That a method of "speeding up" the union of fractures may be developed is probably not chimerical.

The impression formerly prevailed that latent life, such as exists in vegetable seeds and the multifarious bacteria and germs, could survive, even under the most favorable conditions, for but a limited term; but it is now known that temperatures low enough to impede, yet not destroy the germinating principle, will conserve the same for an unlimited period. Svante Arrhenius, the Swedish physicist, has propounded a hypothesis wherein he sets forth that intense cold retards, in certain ratio, such chemical reactions as would cause loss of budding power of seeds. He hazards the proposition that the germinal power of spores would not deteriorate any more during 3,000,000 years if kept at 220 degrees below zero than it would during one single day if kept at 10 degrees above zero.

P. Becquerel is authority for the statement that various seeds of some fifty species had retained

their vitality after having lain in a museum during 25 to 85 years.

Giglioli (see *Nature*, 1895, p. 54) kept seeds in hermetically sealed tubes containing certain dry gases, including such poisons as chlorine, arseniureted and sulphureted hydrogen, and carbon monoxide. He declared that seeds could survive in these poisonous surroundings during the entire period covered by his experiments, namely 15 to 16 years.

Professor Jacques Loeb, H. Charlton Bastian and others have devoted much study to the problem of spontaneous generation. When one reads their conclusions the impression remains that the element of time entering into such a procedure must ever be a bar to the satisfactory elucidation of so abstruse a problem, and that one cannot reasonably hope to reproduce in the laboratory an evolution in which a very long period of time was in all probability of essence.

Pondering the feature which time plays in all physical functions, and considering its appositeness to certain processes in the human economy, should facilitate comprehension of some sporadic pathological recurrences or recrudescences which the physician encounters. Many factors entering into the perplexing periodicity or obscure desultoriness of successive epidemics remain vague. The time element is undoubtedly one determinative agent. Many bacteria are probably aoristically torpid, but what determines the variable periods of rest and activity is beyond our ken. At one time it was generally believed that the severance of tissue from an individual implied prompt necrosis of such structure. Yet Dr. Carrel has accomplished the seemingly impossible by preserving, in a latent state, certain tissues which he had taken from animals. Safeguarding such tissues in sterilized vaseline against vitiation by the air, he was able, after forty days, to implant the same successfully upon or into the bodies of members of the same species. What stayed the ruthless hand of time? What was the animative element dominating the severed structures so that they again functionated when they became integrant parts of a new economy? It is a moot question what elements, at the dawn of evolutionary development, entered into the establishment of the familiar periodicity governing ovulation and gestation. As the time periods approximately correspond with lunar variations, it was popularly believed that the moon had something to do with the monthly (mensis) discharge. Darwin attributed this regularity to the influence of the tides, believing that the food supply underwent changes from week to week, and that the vital functions of individuals existing under such conditions for innumerable generations would probably run their courses in regular weekly periods or multiples thereof. Just why some species should not be governed by the same conditions that led to the establishment of such definite periodicity in others must remain problematical.

It is interesting to note how septenary periods prevail in the generative pendencies of some animals. The period of gestation in dogs is 63 days, in hogs 112 days, in mares 210 days. The pigeon hatches her eggs in 14 days, the chicken in 21 days, the duck in 28 days, the ostrich in 49 days.

It is a familiar circumstance that cerebration takes place at various rates of speed in different individuals and at a variable rate in the same individual under dissimilar conditions. There is a wide range between the time required for mental processes by the child afflicted with aprosexia and the inexplicable rapidity of brain functioning evinced by so-called mathematical prodigies; and between these extremes one notes varying degrees of rapidity or protraction of intellection, almost prompting the use of distinguishing terms, such as reverie and intuition.

Taking one thing with another, time is a regnant element in all physical functions. If the ratio of respective reaction velocities in biochemical concatenations were determinable, a new therapeutic era would be dawning, for procedures might be evolved to stabilize the several counteractive processes, so as to be isochronous or heterochronous *pro re nata*.

Highland Building.

Medicolegal Notes.

Qualification of Expert—"Surgery."—In an action on an accident policy objection was made that a medical witness was not shown to be an expert in the matter about which he was allowed to testify (the beneficiary having claimed that the deceased died from wounds and the insurance company that he died from typhoid fever). It was held that the objection was not well taken. The witness said he was a surgeon; he did not say he was a physician. In a narrow technical sense surgery may consist in the treatment of injuries, deformities, or diseases by mechanical operations only; but a surgeon must know—the law requires him to know—the progress, manifestations, and results of the diseases and injuries which he treats, and hence it was held that the witness said enough of himself to show that he was qualified to speak as an expert of those matters about which he testified.—Maryland Casualty Co. vs. McCallow, Alabama Supreme Court, 75 So. 902.

Illegal Practice of Medicine.—It is held that under the Pennsylvania acts of 1911 and 1914 a person may be convicted of practising medicine and surgery who holds himself out as a "doctor" under the name of a "chiropractic" and professes to treat nervous diseases, nerve displacement, and nerve impingements by thrust handling and manual treatment, and by pressure and heat. The court said, in part: "The literature of the profession, as well as the speech of the common people, understand the practice of medicine and surgery to include the investigation of causes of disease, and by the use of medicines and drugs, instruments, and appliances, to cure, mitigate, and alleviate bodily disease and physical derangements. There never has been and cannot be a complete separation between the practice of medicine and surgery as they have been practised and understood by the most learned in the profession. The principles of both are the same throughout, and no one is fully qualified to practise either who does not understand the fundamental principles of both. The statutory requirements of recent years have been deemed necessary to protect the public from imposition and fraudulent practices, and have resulted in subdivisions into departments, by pretentious specialists, so as to evade the statutory requirements of general professional qualifications. New and coined words are used to represent a particular branch of medicine or surgery, or a departure from recognized methods and practices. In most instances they are deceptive and artful devices to impose on the public and increase the necessity for statutory regulation. . . . This question has been fully considered by the courts of other States, under similar statutes, and all support the conclusion reached by the court below."—Commonwealth vs. Byrd, 64 Pa. Superior Court 108.

Military Medicine.

LETTERS FROM AN M. M. R. C.

THERE is a definite undercurrent of feeling among the men of the Officers of the Medical Reserve that the Government should without delay frame up laws for adequate insurance protection for them. They feel that if they are maimed by any accident received in line of duty they should receive the same pension that is now accorded the doctor of the regular army. They rightly contend that they take the same chances as the latter and should meet the same consideration. There is also considerable feeling that a majority is the highest rung of the ladder so far as they are concerned. It leads to a sentiment that finds expression on the lips of many: "Well, when I get to be a major that will be about all I want to see!" Of course, in the first batch of appointments some men received their commission as major who really could not measure up to a high standard of efficiency. That such mistakes were bound to occur at first is quite excusable and of trivial importance. The training the men are put to and the more or less continuous observance of their characteristics and bearing quickly eliminate the undesirable major from filling a post of responsibility. He will remain major and draw the pay of his rank, but his responsibilities will always be subordinate. It will not be surprising if before long the pipings of discontent now heard in subdued murmurs from many small tongues will find vent in organization and a single authoritative voice will represent the feelings of the Medical Reserve Corps as a whole. The number of men now in this body must be very near twenty thousand at the moment of writing. They already far outnumber the regular army doctors. Each member of the Medical Reserves has more or less political influence in his own home town. Their forces are drawn from every county of the United States. Would it be surprising that a request sent to every senator or representative would have a favorable hearing? I doubt if the regular army can withstand the pressure of what this organization may consider its fair due when the time comes.

There is a great universal feeling of disorganization among the old men of the Medical Officers Training Camp as soon as the time of their probation and training is completed and assignments to active duty at different posts are started. They do not all go out at the same time and the disorganization I speak of affects to a marked degree those left behind and awaiting orders. An extreme irritability and nervousness is noted among this group. They watch every messenger boy coming up to headquarters with telegrams in their hands. Their eyes follow them hungrily, inwardly praying that the message is for them. Their morale, which has slumped since their companions in training have passed on, makes them poor companions for the new officers just arriving in camp for training. It would be much better for the latter if the barrack was swept almost clean of old men before the new ones were taken in. The subject of assignment to duty is one of considerable interest to the medical officer. About the middle of the training course all men are asked to write down their specialty if they have one, their experience in this line, and the position they would like to fill in the army. These questions are only put to the men who are not already assigned to a hospital unit or awaiting results of examination for the regular army. Most of the men set themselves down as being surgeons and ask for field hospital service. What they ask for and what they get are two entirely different things. The probabilities are that they will be assigned to regimental attachment. They may remain in this position for the balance of their time in service or after a month or two will be assigned to some other branch of the service. The most likely situation for a man to do actual operative work would be to be assigned as assistant to a division surgeon. These appointments are few and far between and depend a great deal on how your company commander feels toward you personally and that the same company commander himself is going to be promoted to the rank of division surgeon which is colonel. A regimental attachment, which is the most common assignment, carries the following work with it: sooner or later the surgeon will be assigned to a regular regiment which is either in the field or what is more likely already in barracks in one of the many army posts. The regiment may be infantry, cavalry, or artillery. Besides looking after the men who are ill at this post, he has charge of the officers' wives and children who may need his attention. He also has to supervise the carrying out of the proper sanitation rules prescribed. Before he reaches this final detail he will probably be given service in one of the new cantonments examining recruits and doing sanitation duty. Of course all the army posts of the country will be kept going and in full operation, no matter how many troops are sent over to Europe. This means that many men will not see service on the other side. Their work will be done at home, or in the Philippines, or Honolulu, for, of course, these posts will be kept filled. In connection with the Philippines it will be of interest to some that baldheaded men are undesirable to fill these tropical positions. Every man assigned to regimental work will find himself a part of the following complement: One major, one or two captains, and the same number of first lieutenants. This staff will have direct charge of the hospital corps, which may consist of thirty men and the regimental band.

The man who limits his specialty to one branch is more apt to receive his active assignment to a desirable post than the man who has several specialties. For instance, the man who specializes on the eye will probably be sent to the aviation camp at Mineola, while the man who says that he specializes in eyes, nose, and throat will get an assignment to Fort Sill, Oklahoma, or some other place. The man who says he is a specialist in bacteriology will probably be sent on to the Rockefeller Institute for further instruction. Many wonder that obstetrics should be put down in the list of qualifications you are asked about. The answer is simple. If some colonel or other officer in a fort out West is about to have his wife confined and for some reason does not think very much of the doctor at his post to take charge during this delicate operation, he will send in a request for the latter's transfer and that a doctor capable in midwifery be sent to his post. It is easier for him to do this now

with a new bunch of Medical Reserves to call on than it was before. As in ordinary life, women have their preferences, and if for any reason the post surgeon does not make a hit with them it will not be long before they bring their feelings to the attention of their better half. This will account for the specialist in children's diseases and others that seem unintelligible as pertaining to army life at first. As new situations arise, the men in training camp toward the end of their service are given chances to go on various detachments. In the first class in instruction there was an occasional call for volunteers to go to France. This call is no longer heard.

The Administration of Anesthetics at the Front.—Geoffrey Marshall, from the point of view of the anesthetist, divides wounded men into three main classes: (1) The lightly wounded. (2) Those suffering from serious wounds with more or less shock and hemorrhage, the two factors being commonly associated. (3) Those suffering from a severe degree of sepsis, especially anaerobic infection. The choice of anesthetic depends on which of these classes the patient belongs to, as well as the region of the body injured.

The patients lightly wounded are good subjects for anesthesia, so that the chief desiderata are safety, speed, and convenience. The ideal anesthetic is one by which induction is rapid and recovery complete a few minutes after operation, so that the patient is fit for early removal by ambulance train. Gas and oxygen meet these requirements best. When this method is not available, ether administered as a warm vapor by "Shipway's apparatus," should be used, as both induction and recovery are more rapid than with the open method. Local anesthesia can be employed in only a few cases.

In the more seriously wounded safety is the one consideration, and an anesthetic must be employed which will minimize shock. Spinal anesthesia has not, so far, met the requirements, as shown by an analysis of fifty consecutive cases operated on at a clearing station for wounds of the lower extremities under stovaine anesthesia. This is particularly true in the man who has lost blood and whose wounds are less than forty hours old. A man suffering from the shock of a recently shattered limb and who has to undergo the further shock of an amputation is an extremely unfavorable subject for anesthesia. The mortality can be greatly reduced by the correct procedure. The patient must be put to bed and surrounded by hot water bottles or a hot air bath. No matter how urgent the operation it is useless until the patient has been thoroughly warmed up. Morphine should be withheld before operation or given only in small doses. Gas and oxygen should be the anesthetic used for operation, as results are so much better with this mixture that no other anesthetic is justifiable. If chloroform be used, the patient's condition will deteriorate during the administration, and he will not rally afterwards. With inhalation ether the condition may improve and the blood pressure rise during operation, but there will be a collapse during the next two hours. With intravenous ether the temporary improvement is more striking and the after-collapse more profound and more fatal.

Shock is a condition which still evades precise definition, although seen so commonly in wounded men. The injuries which cause it are almost always severe in themselves. Shock by the various known methods should always be treated before operation. The administration of chloroform, ether, and morphine increases shock.

Operations on the head may be performed under local anesthesia. A solution of novocaine and adrenalin is hypodermically injected into the scalp surrounding the site of injury. When forcible cutting of bone is to be done, hyoscine and morphine should be given an hour before operation. General anesthesia by Shipway's apparatus may be given. A warmed mixture of ether and oxygen is administered through a catheter passed down the more patent of the two nostrils.

In wounds of the chest ether should not be administered to a patient with perforating wound, as it usually provokes fresh intrathoracic hemorrhage. For small operations, such as the resection of a rib, local anesthesia should be used. For more extensive operations, a preliminary injection of morphine, grain 1/6, hyoscine, grain 1/100, and atropine, grain 1/100 is given, followed by a minimal amount of warm chloroform vapor with oxygen.

For wounds of the abdomen the most satisfactory anesthetic is a warmed mixture of ether vapor and oxygen. Easier breathing, diminished heat loss, less vomiting afterwards, as well as rapid and quiet induction at the beginning are obtained. This method also tends to diminish the sequela of bronchitis. By the open method of ether administration, 54 per cent. of these cases developed bronchitis, whereas by the warm vapor method, the percentage of bronchitis was reduced to 14.7.

The patient whose condition is rendered grave by sepsis will stand an amputation far better than the man who is suffering from shock. In the septic case, gas and oxygen again give excellent results, but spinal anesthesia, warm ether vapor, and intravenous ether are also comparatively safe. Chloroform, however, is to be avoided, as it is often followed by a slow fall of blood pressure which ends in death during the twelve hours succeeding operation. —*British Medical Journal*, June 2, 1917.

Application of the Carrel Method to Wounded Evacuated to the Rear.—The Carrel method is known chiefly in connection with the treatment of recent wounds but to-day, according to Guillot and Woimant (*Revue de Chirurgie*, August, 1917), a new question is being asked—"Can the same procedures be applied to the treatment of wounded who have been evacuated to the interior?" The authors outline the technique which they have tested in connection with the new problem, as follows: The only problem is to bring the antiseptic in contact with all the parts of the wound. This has been realized heretofore in connection with recent wounds, *i.e.* those treated in the first 24 hours. If now we have to treat wounds some days old the first requisite under any plan of treatment is free access to all disease foci. This is of course the indication of necessity when failure to do so would be followed by death. One acts thus in the presence of hematomas, foci of gas gangrene, infected fractures, etc., when facilities for drainage are incomplete even though one temporizes when drainage seems to be satis-

factory. The operations necessary as preliminary to the sterilization of these wounds are often severe, necessarily so in comminuted fractures. Recently a surgeon performed five successive operations for the early removal of spiculæ of bone in fracture of the thigh. These were all secondary interventions after fresh infection had occurred. All the patients died. In interventions of this type the authors have always used bacteriological control and the degree of infection in these foci is very high. Let us suppose that at the outset, before operation, each bacterioscopic field contains on an average 10 bacteria. After the intervention the so-called bacteriological curve rises hourly until within a few hours it passes into infinity. Hence an ill considered intervention must be looked on as favoring in the highest degree a proliferation of microbes, as a consequence of the septic field and weakened resistance. In one curve plotted the patient, who had necrotic bone in his fracture, had had his bacterial index reduced to 6 per field by treatment. It was now thought necessary to perform sequestrotomy, after which the count, as shown by the curve, was soon equal to infinity. In such cases sterilization could reach only a certain degree because of the necrosis, and speaking generally there should be no secondary operation until disinfection has reduced the risk to a minimum.

In the great majority of cases the method of Carrel may be trusted in these old infected wounds. One must first disinfect, as in recent injuries, laying bare all recesses. Every other day irrigation is discontinued until a representative smear can be obtained. This should be taken at the proximity of any necrotic focus or denuded bone, should such exist. An everage should be obtained from three microscopic fields and the curve started. Should the average number per field decrease persistently smears should be taken daily. If a point is reached when only one bacterium is formed in 3 or 4 fields, it is considered safe to close the wound.

But while thus caring for a wound we sometimes note that the descent of the curve is interrupted; it rises and forms a plateau. This means invariably that there is a source of infection in the wound depths—a bit of cloth, a gangrenous focus in the soft parts, an osteitis, a sequestrum. Such foci should be suppressed. Irrigation and disinfection have done what they can. No time must be lost, for the focus is bound to increase. The operation once performed, irrigation is resumed until the wound can be closed. In fracture cases proper treatment must be maintained. All immobilizing dressings are abandoned in favor of the American plan of extension plus suspension. Not less important than bacteriological control is the correct preparation of Dakin's solution. First the content of hypochloride must be kept at from 0.45 to 0.50 per cent. Second, the solution must contain no caustic soda.

Additional Red Cross Gifts.—The Council of the American Red Cross announces an appropriation of $500,000 for the establishment of a Hospital Supply Service in France, to be under the direction of the Red Cross Commission in France of which Major Grayson M. P. Murphy is head. This step marked the further centralization of relief activities in France under the Red Cross through which it is hoped to make a more expeditious distribution of medicines and hospital supplies to the various war hospitals. Another appropriation announced by the Council of the American Red Cross is one of $300,000 for relief work in the Near East through the American Committee for Armenian and Syrian relief. Estimates state that there are more than 2,000,000 people in western Asia in need of direct and continued help from America.

Red Cross Mission in Rome.—The American Red Cross mission to Italy has arrived in Rome, where it was received with great cordiality. Arrangements have been completed for the mission to go to the front to inspect the sanitary organization there. The members of the commission will be received by General Count Cadorna, the Italian Commander-in-Chief, and will have an audience with the King.

Germans Bombard American Hospitals.—On the night of September 3, German airmen made an atrocious attack on two British-American hospitals on the French coast, killing four Americans and wounding a dozen others. The Harvard and the St. Louis hospital units were in charge of these hospitals. First Lieutenant William T. Fitzsimmons, adjutant to the colonel commanding one of the Harvard units, was instantly killed. The other victims were privates. In addition to those killed, three first lieutenants and one nurse were wounded. One of the bombs struck a tent filled with wounded men, and the legs of one of the wounded men were blown off. The officers and nurses showed signal bravery, ignoring all personal danger and continuing in the performance of their duties heedless of the explosions around them. Ten of the sixteen persons injured were hospital patients.

War Hospital Opens Second Ward.—The War Demonstration Hospital of the Rockefeller Institute for Medical Research has opened a second ward. Patients are to be admitted to this ward who have obstinate infections that have resisted treatment by ordinary methods, and those who have compound fractures, chronic osteomyelitis, or varicose leg ulcers. It is proposed to demonstrate the efficacy of the Carrel-Dakin method of treatment in these conditions.

Ambulances for Italy.—The Committee of American Poets, of which Robert Underwood Johnson is chairman, is endeavoring to raise $100,000 for the American Ambulance for Italy. The committee already has sufficient funds for the purchase and maintenance of several ambulances, and has cabled to have them put in the field at once.

Gives House to Red Cross.—Mrs. Nicholas F. Brady has presented the Colony Clubhouse, at Madison Avenue and Thirtieth Street, New York, which she recently purchased for $400,000, to the American Red Cross, to be used as headquarters for the New York district for the period of the war.

Ambulances for Russia.—The Red Cross announces an immediate shipment of one hundred and twenty-three ambulances to Russia as a part of its program to give effective assistance to that country. It is reported that in the Eastern front there are only 6,000 vehicles to transport the wounded, while on the French front, which is only one-third of its length, there are 75,000 ambulances.

APPLICATION FOR APPOINTMENT IN THE MEDICAL RESERVE CORPS, UNITED STATES ARMY

.....

....., 191

To the Surgeon General, U. S. Army,
Washington, D. C.

Sir:

I hereby make application to be examined for appointment in the Medical Reserve Corps, U. S. Army, and inclose testimonials as to my character and habits.

I certify that to the best of my knowledge and belief I am laboring under no mental or physical infirmity or disability which can interfere with the efficient discharge of any duty which may be required of me if appointed in the Medical Reserve Corps, U. S. Army, and that the answers given to the interrogatories below are true and correct in every respect.

I furthermore state my willingness to proceed to such point for examination as may be designated by the Surgeon General, with the understanding that the journey entailed thereby must be made at my own expense.

INTERROGATORIES

Where were you born? (Give State and city or county; if foreign born, give country.).....

.....

What is your name *in full* (including your full middle name):.....

What was the date of your birth?.....

When and where were you naturalized? (For applicants of alien birth only).....

Are you married or single?.....Have you any minor children; if so, how many?.....

What is your height in inches?.....Your weight, in pounds?.....

Give the nature and dates of all serious sicknesses and injuries which you have suffered:.....

.....

If either parent, or brother, or sister has died, state cause and age in each case:.....

Do you use intoxicating liquors or narcotics? If so, to what extent?.....

Have you found your health or habits to interfere with your success in civil life?.....

What academy, high school, college, or university have you attended? State periods of attendance from year to year, and whether you were graduated, giving date or dates of graduation:.....

.....

Name and other educational advantage you have had, such as private tuition, foreign travel, etc.:.....

.....

Give all literary or scientific degrees you have taken, if any, names of institutions granting them, and dates:.....

With what ancient or modern languages or branches of science are you acquainted?.....

How many courses of lectures have you attended? Names of colleges and dates:.....

.....

When and where you graduated in medicine?.....

(Fill this out and send it to the Surgeon General, U. S. Army, Washington, D. C.)

Have you been before a State Examining Board? If so, state when, where, and with what result:*.....

.....

Are you a member of any State medical society? If so, give its name.....

Have you had service in a hospital? If so, state where and in what capacity, giving inclusive dates of each kind of service:.....

What clinical experience have you had in dispensary or private practice?.....

.....

Have you paid particular attention to any specialty in medicine; if so, what branch?.....

What opportunities for instruction or practice in operative surgery have you had?.....

.....

Have you previously been an applicant for entry into the United States service? If so, state when, where, and with what result (if rejected, state why).....

Are you a member of the organized militia? If so, state with what organization and in what capacity:

.....

Have you been in the military or naval service of the United States as cadet or otherwise? If so, give inclusive dates of service with each organization, designating it.....

What occupation, if any, have you followed other than that of student or practitioner?.....

What is your present post-office address?.....

What is your permanent residence?.....

Signature.....

The correctness of all the statements made above was subscribed and sworn to by the applicant before me this.....day of.....A.D. 191

[SEAL] .....

*This application must be accompanied by a certificate from the proper official that the applicant is duly registered to practise medicine in the State in which he resides.

THE DUTY OF THE MEDICAL PROFESSION IN TIME OF WAR.

IT is a difficult problem that confronts many physicians at the present time, pulled as some are by duty in three directions. In the first place is the loud and insistent call of patriotism, which seems to be—the country needs you! Then there is the call of the community—your patients need you! And finally there is the domestic call—your wife, your children, or may be your aged parents need you! Is it to be wondered at that many patriotic and conscientious men are still hesitating as to which is the true duty call, or can we be surprised that some may have chosen wrongly in responding to the summons to war? The country calls with loud voice and imperatively; the army needs medical officers and it must and will have them. But it does not need every man; unless the war is prolonged far beyond the conservative estimate of those best qualified to guess, the number of physicians to be taken from civil life will not exceed 25,000 or about 17 per cent. of the registered physicians of the country—say one in six of the total. This number could easily be secured if only those, but *all* those, whose circumstances are such that they can be spared temporarily should offer themselves for service; they might not all be wanted now, but it would simplify matters greatly if the Surgeon General knew that there was still a body of available physicians subject to call in case of further need.

But the problem of choice remains, and it is here that what has been called the New York idea offers a solution. This is the plan recommended by the Medical Section of the New York State Committee of National Defense in its suggestion of a selective draft of physicians, referred to in the statement from its secretary published in another column (see p. 468). As the petition there mentioned has been printed only in the *Journal of the American Medical Association*, and has probably, therefore, been read by but a limited number of physicians in this State, we publish the same in connection with the statement referred to. We do not quite like the term selective draft; mass volunteering is better and more truly expresses the plan that would secure the needed quota of available medical men. As we have said before, we do not believe conscription will be necessary, but what is necessary—absolutely necessary to prevent suffering and injustice, is to determine who among the 140,000 or more physicians of the country should go and who should stay. This selection can best be made by a medical census such as that of New York State, the profession as a whole offering itself to the service of its country, some of its members to go to the war, some to remain in civil practice, some to retain their teaching positions, and others to stay at home perforce because of age or physical incapacity. The eligible list prepared as a result of this census in every State would be drawn from by lot in the office of the Surgeon General, and we have faith enough in the patriotism and self-sacrifice of the medical profession of this country to believe that few so chosen would close their ears to the call of duty. If they did, if the test should shame us all by exposing our younger men as slackers and cowards, then the draft would have to come. We are at war and every citizen must serve the Nation in some capacity or other—if not willingly then unwillingly, but serve he must.

At the annual meeting of the American Medical Editors' Association in June, it was suggested that every journal publish once in each of the succeeding three months the application blank for appointment in the Medical Reserve Corps. We have published this in three previous issues and do so once more, urging every one of our readers who knows himself to be eligible to fill out the blank at once and t fulfill the obligations under which he rests to the Nation for its protection and for the benefits which his citizenship has conferred upon him.

WHY THEY LAUGH AT ALIENISTS.

To the newspaper humorists and—by a natural sequence—to the man in the street, the alienist has long been a legitimate object of ridicule. It has been the fashion to call him a "mad doctor" in a manner suggestive that the adjective belongs to the doctor rather than his patients; newspaper accounts of expert medical testimony are wont to reek with humor, and when the insanity defense is put forward in a murder trial the Fourth Estate surpasses itself in facetiousness. Now where a thing exists as consistently as this, there must be some strong reason for it. Of course, it is easy to take the attitude of ridiculing the laughers themselves, we can dismiss them with angry contempt as ignoramuses, but such reactions are after all evasive. Mankind does not employ such a tremendous weapon as laughter—the only effective weapon, according to Langhorne Clemens, which it possesses to combat the evils of things as they are—without some object, even if that object be not immediately perceptible to the scoffers themselves.

It behooves the profession as a whole, then, and

the neurologists and psychiatrists in particular, to cast about for the reason of this mirth, and, should it be found to have its springs in a real fault, to bestir ourselves to discover an adequate remedy.

We are all familiar with the sorry spectacle of the usual insanity defense, where Professor So-and-So followed by others of his kind with a formidable array of whiskers and titles takes the stand and gives his polysyllabic opinion that the prisoner is insane; he is then quizzed by the opposing lawyer and, by a series of innuendoes, omissions, and cleverly worded questions, made to appear ridiculous so that he finally departs in confusion. Then the experts on the other side, equally hirsute and erudite, take the stand and swear that the prisoner is of sound mind; they are cross-examined, made to appear ridiculous, and sit down in their turn in confusion. As the lawyer for each side addresses the jury, he is careful to hold the experts of the other side up in an unflattering light, the judge in his instructions is likely to have a mild fling at expert testimony in general, the jury calmly disregards both sets of experts and forms its opinion on "good, sound, common-sense" which, as every alienist knows, is worth about as much in an estimate of mental status as the opinion of a man who had never seen a diamond would be in Kimberley.

Now the reason for this unfortunate state of affairs is simple and is merely this: the present system of expert testimony is all wrong. We all know how careful a judge is, when trying a case, to avoid anything which might even appear like bias toward one side or the other. It is not uncommon, indeed, to see a judge leave the bench and turn the case over to some other jurist simply because he has discovered that he had recently held a conversation with the attorney on one side, during which a feature of the case was mentioned casually. A judge does this because he recognizes the frailties of human nature and because he knows how easily a man may be prejudiced, unconsciously though it be. Let us consider then the alienist who is called to the stand by a certain side to whom he looks for his money —to whom he stands in fact in the relation of employed to the employer. He knows that the lawyer who has employed him expects him to testify in a certain way and asks his questions, not to bring out all aspects of the truth, but to develop so much of the truth as will serve his purpose. It is asking too much of human nature, then, to expect the expert to steer his skiff safely between the Scylla of favoring his own side and the Charybdis of bearing a little to the other side in an effort to appear impartial. Either course is wrong, indeed.

It is this fallacy, then, that the humorists are unconsciously attacking, the fallacy that human beings can be absolutely impartial in an issue where their interests are strongly engaged. So long then as this sophistry continues to masquerade in our law courts as a verity so long will the "mad doctor" be an object of ridicule. It is hard, perhaps, on the individual alienist, but it is the best thing which could happen to the institution. In the course of time this weapon of laughter will pry loose the whole pernicious system and send it crashing down into the abyss where lie trial by ordeal, witchcraft, and other outgrown garments of civilization.

A NEW BLOOD SYMPTOM IN MALARIA.

SINCE the plasmodium often occurs in the blood without the development of malaria, and since the research for the parasite is often attended with negative results at the hands of the inexperienced (at least this was the case not so many years ago) any new and simple blood test such as can be made by the nonexpert, must be of value. The old "pigmented leucocyte" test rendered good service many years ago in the diagnosis of past malaria and Dr. Hirschfeld, in the *Correspondenz-Blatt für Schweizer Aerzte,* August 4, has just made a preliminary announcement of the following new resource as based on these facts.

A thin smear made from the blood of an anemic malarial subject will not spread evenly over the glass, apparently because of a tendency of the erythrocytes to clump and adhere. If one makes a thicker smear and studies it with the lens there is absence of homogeneity, the blood having granulated irregularly on the glass. This phenomenon suggests at first rapid coagulation, but is shown to depend on some hitherto unknown property of the blood. The more severe the infection and cachexia the more pronounced the clumping and adhesion. It is not yet claimed that this behavior does not occur in other infections, for it stands in close relationship with the anemia associated with chronic disease.

If an anticoagulant such as sodium oxalate is added to blood obtained from a vein the erythrocytes drop quickly to the bottom of the container and it is also evident that the same tendency is present in non-oxalated blood, for when coagulation is permitted the coagulum shows certain peculiarities due to the relatively small number of erythrocytes in proportion to plasma.

The author has timed the precipitation of the erythrocytes in oxalated blood and finds that the greater the anemia the shorter the interval. Moreover, this rapid precipitation brings about a granulation of the erythrocytes, which is in turn responsible for the peculiar behavior of malarial blood in smears. Hirschfeld satisfied himself that this behavior does not represent autoagglutination because the clumping which occurs is not a true agglutination, *i.e.* the erythrocytes do not really cohere. If the precipitate is shaken up the cells separate and promptly sink again. The author is making an intensive study of the subject which, we may hope, will not only add to our diagnostic resources but will very probably augment our general knowledge of the pathology of the blood.

Physical and Intellectual Energy After Prostatectomy.

It is the view of some urologists that after ablation of the prostate there is some enfeeblement of the physical and intellectual vigor. It would be well if this claim could be demonstrated to be true or false, for the operation is rapidly becoming popularized. The operation in reality consists of the enucleation of an intraprostatic adenoma, the ejaculatory ducts being left intact. However, the perineal operation is a true prostatectomy. In an article by Legueu, abstracted in the *Journal de médecine et de chirurgie pratiques* for June 25, this author relates that his record has reached 450 cases. A partial aspect of the problem is the effect of perineal prostatectomy on the reproductive apparatus. In this form of intervention the nerves are divided, the verumontanum is destroyed, and the ejaculatory ducts are divided. Sexual frigidity after the perineal operation is but natural. It is entirely otherwise with a simple enucleation, when all the above structures remain unmolested. The patients have been freed from burdensome disabilities, and feel younger and more sprightly. In addition, the organism has been disembarrassed of the toxic product secreted by the adenoma, the existence of such a substance having been proved by Gaillardot. It is, for example, hypotensive, and further causes eosinophilia. Suppress the adenoma, and behold the extraordinary regeneration of the patient! How, then, can there be visible, asks Legueu, for a time at least, any evidences of a weakened body and mind? In but one of the author's 450 cases did the operation fail; *i.e.* retention persisted. It is especially in the mind, in the morale of the individual, that prompt improvement is most apparent. Before intervention, patients are often torpid, interested in nothing, and do not even react when intervention is decided on. Legueu has never seen a case of postoperative insanity in prostatectomy cases. He would be inclined to believe that in such a case there had been a preoperative psychosis. The author nowhere mentions any late or remote failure of the forces as a result of adenoma suppression.

A New Mode of Treating Leucoplakia Buccalis.

For the average practitioner, smoker's patches on the tongue and buccal mucosa do not represent a disease process but the sequel of one, corresponding to a superficial but unmistakable cicatrization which is irremediable. That intensive treatment of syphilis may cause occasionally the disappearance of similar lesions has, however, been noted. There are, perhaps, some lesions in which the sclerosis is amenable to specific measures associated with the most careful mouth hygiene and appropriate topical treatment. But attempts to cure these lesions as a class in the interest of cancer prevention usually fail. There is, moreover, a belief in some quarters that the refractoriness of leucoplakia to treatment is not uncommonly due to the fact that a condition of so-called precancer is already present. The very slow evolution of cancer on a leucoplasic basis is well known. During the present year, Averon, a French graduate in medicine, took as the subject of his thesis a new plan of treatment of leucoplakia. This work is reviewed by Bernard in *Le Progrès Médical* for August 4. With proof of likelihood of syphilis, the first measures to take refer to constitutional treatment of the latter. Only when this fails should we proceed to local measures. If we are dealing with the supposed sequelæ of mucous patches, the treatment by caustics and alteratives, so useful at times in the latter, might be employed; but since the author assumes that the lesions cannot be regarded as necessarily syphilitic, he holds that it is best to employ no irritant which could perhaps hasten the appearance of cancer. Measures sanctioned in suitable cases are destruction with the cautery, curettage, plication, extirpation, and decortication. The latter alone is applicable in the diffuse type, and has been used by Morestin. A new resource advocated and practised by the author and Tzanck is interstitial injection. The substances used appear to be mercurials, but the reviewer fails to enumerate them. An integral part of the procedure is local anesthesia with cocaine or stovaine and adrenalin. It is said that the injections cause an exfoliation of the leucoplasic patch, with resulting healing without scar of the newly-formed raw surface. It is not claimed that this plan of treatment will do away with all others. It is meant to be adapted chiefly to military requirements of the present time, and may undergo modifications for civil practice. Thus conceived, it is claimed to be a simple, harmless resource, suitable for the treatment of a large number of patients at one time.

Syphilis and Cancer.

Many writers and clinical observers have suggested a relationship between syphilis and cancer. The indirect consequences of syphilis, doubtless, predispose to numerous specific diseases. Now that in Europe syphilis is extremely prevalent, attention has been drawn especially to the point. Mr. W. Stuart-Low in the *Lancet* of September 20, 1902, in a paper entitled "Mucin and Malignancy," showed that in fifteen fatal cases of cancer of the throat a history of syphilis had been established, while during the past fifteen years he has investigated many more cases, in which an equally unequivocal history had been proved. The same author, writing in *The Practitioner* of August, 1917, states that at the present time he has twelve instances of cancer of the throat under observation, and in every one syphilis has been shown to have been contracted in earlier years. Moreover, he further states that since the introduction of the Wassermann test he has made a point of applying it, and has invariably found the reaction positive. The predisposition to cancer of the throat brought about by the occurrence of syphilis is mainly due to local injury inflicted on the tissues of the throat by the usually severe incidence of the secondary stages in that area. As a matter of fact, the disease leaves the mucous membrane in such a condition that it is less resilient, less yielding, and more likely to be abraded. Also, not being sufficiently lubricated, owing to the diminution of mucus, it is readily irritated by acid saliva, too hot food, and tobacco smoke. It is not improbable that, as Stuart-Low and others think, syphilis may prepare the field for cancer.

News of the Week.

A Diploma Mill in New York.—The New York City Health Department, through the excellent detective work of one of the inspectors of the Bureau of Foods and Drugs, has unearthed a very cleverly executed swindle. The investigation which began last June in connection with the discovery that large quantities of spurious neosalvarsan were on the market have finally reached a climax. It has been found that the traffic in fake neosalvarsan and narcotic drugs has been carried on to a great extent by one group of individuals, and the leader of the gang has now been indicted. In the course of the investigation it was discovered that the man's pernicious activities were by no means confined to the sale of a worthless preparation of table salt and a little yellow coloring matter as neosalvarsan, but that he was also operating a "diploma mill." The first of the unlicensed doctors to be apprehended affirmed that he paid $1,500 for a diploma which upon examination proved to be fake. He was, however, assured that he would have no trouble in practising without a license as the proprietor of the diploma factory was an inspector of the New York State Medical Society, in proof of which he showed a written appointment from the counsel of the society. The diploma purported to be from the Southern Medical College of Atlanta, Ga. The man had also a license claimed to have been issued and signed by the Eclectic Medical Examining Board of the State of Georgia. The victim paid $1,500 for his diploma, and there is evidence to show that another one sold for $1,600. A number of "diplomas" signed and ready for delivery with the exception of the purchaser's name were confiscated by the Department of Health. A number of others are believed to have been sold and at least three other "doctors" in the city are under suspicion of practising under their authority.

Street Fatalities in August.—There were during the month of August 75 deaths from street accidents in New York City, 14 of which, however, resulted from July accidents. This is more than double the number for the corresponding month of 1916. As usual the heaviest death toll was of children, there being 34 boys and girls killed. Of the 75 deaths 19 were caused by automobiles; motor trucks caused 13, horse-drawn vehicles 9, street cars 7, and the remainder were the result of collisions and miscellaneous accidents. The report of the National Highways Protective Society fixes the fatalities for the State, including New York City, at 140 persons, 59 of whom were children under 16 years of age. About one-third of these fatalities were due to automobile accidents.

Report on Drug Cases.—The Chief Statistician of New York City, Charles W. Strong, has submitted a report showing that in the first six months of 1917 1,242 drug cases were disposed of in the City Magistrates' Court. Of these 1,104 were men and the rest women. Of 175 drug users over whom the city magistrates have summary jurisdiction, 138 were males and 37 females. All of these were sent to hospitals for treatment. Of 471 drug distributors arraigned for violation of the public health law 424 were men and 47 women. Of 392 felony charges against dealers in narcotics, 339 defendants were men and 53 women. Six men were held for the Grand Jury, the remainder being ultimately charged with misdemeanors.

Japanese Will Fight Typhus in Roumania.—A Japanese medical corps of one hundred men has gone from Yokohama to assist in the effort to control the epidemic of typhus fever in Roumania. Dr. Kuranosuke Mogi is chief of the corps, which is in three divisions, each having a head. These divisions are: internal diseases, surgery, and epidemics. The headquarters of the detachment will be at Jassi. The corps has planned to remain in Roumania eight months.

Tuberculosis in Berlin.—The recently published vital statistics for the city of Berlin for the months of March, April, and May show a 56 per cent. increase in the number of deaths from tuberculosis as compared with the same months of 1916. The statistics for the winter months likewise showed a marked increase in pulmonary tuberculosis and other diseases of the respiratory tract.

Poliomyelitis in New York State.—During the month of July this year there were but 41 cases of poliomyelitis reported in the entire State of New York, 24 in New York City and 17 up-State, while preliminary returns for August show but 14 additional cases in New York City, and 30 in the rest of the State. This is in striking contrast to the 4,000 cases reported during July of 1916 and 6,000 during August, 1916. The cases have been scattered over the State with no apparent center of infection.

Epidemics in Germany.—A dispatch from Geneva states that dysentery, typhus, and scarlatina have been prevalent in the Rhine towns. The frontier at Basle is practically closed. All travelers coming from Germany are required to undergo medical examination and neutrals crossing the frontier into Germany are warned to take precautions.

Typhoid Fever on Staten Island.—An outbreak of typhoid fever is in progress in the West Brighton district of Staten Island. There are at the present time over thirty-five cases being treated in the hospitals and about forty additional cases are under observation as suspects. The Health Department has sent out a warning to about 4,000 residents not to eat raw food and to be careful of their milk supply. Officials of the State Department of Health have offered their assistance in controlling the epidemic.

The United States Food Administration announces the creation of an advisory committee on alimentation, the purpose of which is to gain the active cooperation of experts in the determination of policies of food control from the standpoint of the science of nutrition. The committee consists of C. L. Alsberg, Russell H. Chittenden, C. F. Langworthy, Graham Lusk, LaFayette B. Mendel, and E. V. McCollum. Dr. Alonzo E. Taylor, Dr. Ray Lyman Wilbur, and Dr. Vernon Kellogg, members of the Food Administration, are ex-officio members of this committee. It is believed that through the advice and cooperation of this committee, representing specialized workers in the various correlated departments of medicine, the administration of food control will be enabled always to work for the best interests of the health of the different classes in different sections of our country.

Further Investigation of Germs in Court Plaster.—The Government's Hygienic Laboratory at Washington announces that the germs of tetanus have been found in two of thirteen samples of court plaster purchased in Washington and in one sample from the Ohio State Department of Health. The Public Health Service announces that there is no ground for believing that the contamination was intentional and expresses the belief that it may have occurred during the process of manufacture or subsequently by careless handling. In the course of this investigation it has been shown that court plaster is not clean in the surgical sense. Thirty-seven white mice died of inoculation from cultures from the specimens submitted by the Ohio State Health Department.

Safety Congress.—The Fourth Annual National Exhibition of Safety and Sanitation was held during the past week in the Grand Central Palace, New York, under the auspices of the American Museum of Safety and the National Safety Council. The exhibit included all possible kinds of appliances for accident prevention, fire prevention, and sanitation. Statistics show that during last year 22,000 workmen were killed in American industrial accidents and that more than 1,500,000 were injured so that they had to lose time from their work during the year. Of this number 600,000 were incapacitated for more than four weeks. It is estimated that the cost of these accidents is $600,000,000 a year and that 70 per cent. of them are preventable.

The Bronx County Medical Society will hold a special meeting on Wednesday evening, Sept. 19, at 8.30. The paper of the evening will be on "The Public Duties of Physicians," by Dr. S. Dana Hubbard, and will be discussed by Drs. Haven Emerson, H. B. Waters, A. J. O'Leary, and Lewis Chargin.

New Health Administration for Brooklyn.—Beginning with September 7, Brooklyn entered upon a separate supervision of all health affairs within its borders. For some time past this borough has insisted that there should be an expanded departmental unit of health administration established in Kings County and this wish has finally been acquiesced in. Dr. B. Frank Knause has been named deputy commissioner and sanitary superintendent of the Department of Health, at a salary of $6,000 a year, and will be clothed with the full power of the New York Health Department. Dr. Herman Tapley Peck has been appointed assistant sanitary superintendent, holding a position similar to the other borough superintendents, at a salary of $4,080 a year.

Dr. Lewis R. Harris has been appointed director of the Bureau of Preventable Diseases of the New York City Health Department to succeed Dr. Bertram Waters, who has resigned from the Department of Health to resume his private practice.

Dr. Elliot Washburn has resigned his position as superintendent of the State Sanatorium at Rutland, Vt., to accept the superintendency of a general hospital having 600 beds at Kansas City.

The Montefiore Home, New York, has been the recipient of a bequest of $1,000 under the will of Julian A. Hellman. The residuary estate of the testator is to go to Mount Sinai Hospital. This will probably amount to about $40,000.

United States Civil Service Examinations.—The United States Civil Service Commission announces the following open competitive examinations: An examination for men only to be held on October 3, 1917, to fill the vacancy of pathologist in Freedman's Hospital, Washington, D. C., at $2,000 a year. Future vacancies requiring similar qualifications will be filled from this examination. Applicants must be graduates of a medical college of recognized standing and have had at least one year's experience in a pathological laboratory.

An examination is also to be held to fill vacancies in the positions of physician in the Indian and Panama Canal Services, acting assistant surgeon in the Public Health Service, surgeon in the Coast and Geodetic Survey, and in positions requiring similar qualifications in other branches of the service. The salaries of these positions range from $1,000 or $1,200 a year to $1,800 a year with certain additional allowances. On account of the urgent needs of the service, applications will be received at any time.

An open competitive examination will also be held for scientific assistant in public health work for men only. In the Grade 1 positions the salaries range from $1,500 to $2,000 a year and in Grade 2 positions from $900 to $1,500 a year. The duties of appointees in the first grade will be to assist in making epidemiological and sanitary surveys to determine the prevalence and causation of disease; the duties of the second grade are similar but under supervision. The duties in either grade require knowledge of local conditions and the ability to meet and deal with the people of the locality. Further information with reference to these various examinations and the time and places in which they will be held may be obtained by applying to the Civil Service Commission, Washington, D. C. Applicants should apply for Form 1312, stating the title of the examination desired.

Examination for Assistant Surgeons in Navy.—Examinations for assistant surgeons for permanent appointment to fill existing vacancies in the Medical Corps of the Navy will be held throughout the country September 17. The permanent authorized strength of the corps is 828 and 68 vacancies are to be filled. A number of temporary appointments will also be made from those falling outside of the first 68. Further information with reference to these examinations may be obtained through the Naval Medical School at Washington, D. C.

Obituary Notes.—Dr. HENRY NASH READ died at his home in Brooklyn, N. Y., September 2, aged 69 years. He was a graduate of the Long Island College Hospital, in 1870, attending pediatrician to the Long Island College Hospital and the Sheltering Arms Nursery, and consulting physician to the Bay Ridge Hospital.

Dr. JOHN T. COOPER, a graduate of the Grand Rapids Medical College, in 1902, died at his home in Muskegon, after a lingering illness, on August 20, aged 55 years.

Dr. ELIZABETH FOLLANSBEE, the first woman physician to practice medicine in Los Angeles, died in that city, on August 23, aged 78 years. She was a graduate of Jefferson Medical College, Philadelphia, in 1877, and professor emeritus of pediatrics of the University of California.

Dr. WILLIAM HENRY REEDY, a graduate of Rush Medical College, in 1876, died at his home in Bloomington, Ill., August 20, aged 69 years.

Dr. JOHN ADAMS COLLIVER, a well-known practitioner of Los Angeles, a graduate of the University of California Medical Department, in 1899, died from an attack of pneumonia following two major surgical operations, at the age of 45 years.

Dr. JOHN MORGAN SIMS, a graduate of the University of Louisville, in 1892, and a practitioner of Collinsville, Ill., died suddenly on August 16, aged 49.

Dr. DAVID G. ALLEN, past assistant surgeon, U. S. Navy, died on the U. S. S. *Panther* on September 5, 1917. He was born at Savannah, Ga., August 10, 1879, and was appointed assistant surgeon in the navy on June 15, 1908.

Dr. PHILIP WILFRED TRAVIS MOXON, a graduate of Harvard Medical School, in 1901, and a practising physician of Brooklyn, N. Y., died September 3, aged 43 years.

Dr. BENJAMIN STURGIS VAN ZILE, a graduate of Bellevue Hospital Medical College, in 1875, died at his home in Brooklyn, N. Y., on September 3, aged 73 years.

Dr. FERGIS S. HALL, a surgeon during the Civil War, and for many years a practitioner of medicine in Orlando, Fla., died on August 26, aged 83 years.

Dr. WILLIAM F. O'BRIEN, a graduate of Tufts College Medical School, in the class of 1904, died of typhoid fever at his home in Pawtucket, R. I., on August 28.

Dr. WILBUR C. RICE of Zephyrhill, Fla., was accidentally drowned while bathing on August 27. He was 37 years of age and graduate of the University of North Carolina, in 1907.

Dr. DAVID MCINTYRE, a graduate of New York University Medical College, in 1881, died at his home in South Boston, on September 2, aged 60 years.

A POSSIBLE PHYSICAL BASIS FOR INEBRIETY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The following incident will interest many persons. It presents positive evidence of the physical character which is back of the habit in a number of persons who suffer from inebriety. A boy ten years of age received a severe blow on the nose, and was treated for a considerable time, ending in recovery. Two or three years afterwards he developed an unusual liking for spirits, particularly wines and beers. All through his school career he was noted as a drinker, never intoxicated, but always using wines and spirits whenever an opportunity occurred. He went into business and was very successful, drank steadily but more guardedly as he became older, using spirits only at night. He made several attempts to recover but failed, and was an object of great solicitude to his family and business associates. His drinking was continuous, and although the effects were not very pronounced he aged rapidly, and was becoming more and more incapacitated. Finally a suspicious discharge from the nose sent him to a surgeon, who removed a depressed turbinated bone, the condition having evidently been of long duration. He recovered, and with this an aversion to spirits came on. He became a total abstainer, and expressed his wonderment that he could not stop before. He is now in good health, and although five years have passed by he is living in the same conditions, becoming more and more emphatic in his opposition to the use of spirits. It seems evident that the injury he received in his youth was an active cause for his use of spirits, and when this was removed the desire for spirits stopped. This suggests an unworked field of study for the physician.

HARTFORD, CONN.

Correspondence

STATEMENT REGARDING THE SELECTIVE DRAFT OF PHYSICIANS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In its issue of August 25, 1917, page 653, the *Journal of the American Medical Association* on the request of the chairman of the New York State Committee of National Defense, Medical Section, printed the petition for selective draft drawn up by that committee. The *Journal* preceded the copy of the petition by an explanatory introduction which states that "a committee was appointed to draw up a petition to the Congress of the United States to be circulated for signatures and then presented to Congress." Note, please, the last four words. The introduction also states that "Letters have been drafted . . . presenting the petition and urging that it be signed and presented to Congress." Again, note the last four words!

The point is just this: The New York State Committee of National Defense has never urged upon any man or organization or institution, that this petition be presented to Congress, and any statements to the contrary are either mistakes or misrepresentations. Furthermore, it is not and has never been the intention of this committee to present to Congress the petition for a selective draft of physicians. On the contrary, it was and is the intention of this committee to present the petition, after securing all the available signatures of physicians in New York State, to the Medical Section of the Council of National Defense.

Undeniable and (to a careful observer) unmistakable evidence of that intention was expressed in the minutes of the committee meeting on July 2 at which the petition was authorized. A copy of the minutes was sent to the Medical Section of the Council of National Defense on July 10, 1917, and the paragraphs referred to are quoted below exactly as they appear in these minutes:

"The secretary moved that: The New York State Committee of National Defense recommends to the Medical Section of the Council of National Defense the institution of a federal classification of physicians similar to that of New York State and that measures be instituted to secure the necessary federal legislation authorizing a selective draft of physicians based upon such classification, which draft shall provide exemptions of: (1) Those with too many dependents—75 per cent. dependent on their professional income; (2) those disqualified by health or age; (3) those needed for public health continuance; (4) those needed for medical education; (5) those needed for hospitals and clinics, and (6) those needed for isolated communities, provided

that such draft automatically exempt physicians as a class from the provision of the present general draft law.

"There was explanation of the motion as follows: That it had no reference to the necessary 2,200 men from New York State at the present time, but that it was a measure for the eventual fair selection of the men that will ultimately be required.

"In order to get the matter of a selective draft of physicians properly before the Council of National Defense as representing not alone the unanimous opinion of the State committee, but also the overwhelming opinion of the profession at large, it was suggested that the committee draw up a strong petition to the President of the United States and to Congress which petition the members of the committee should sign and which should be circulated, through the county committees, for the signatures of the great body of physicians in the State of New York."

Enough misunderstanding of the object of this petition has arisen to make desirable an authoritative statement that this is in no sense an attempt to have conscription forced upon the medical profession from outside—as some men have apparently believed. On the contrary, its adoption will preclude the possibility of any such undesirable action and will at once afford an orderly system of furnishing those fittest for medical officers to the army and of retaining in their communities those physicians most needed at home.

The New York State Committee of National Defense, Medical Section, requests you to publish this statement in justice to the twelve hundred or more physicians of this State who have already signified their approval by signing this petition. Any further information desired will be gladly furnished by this committee.

F. T. VAN BEUREN, JR., M.D.
Acting Secretary, New York State Committee of National Defense, Medical Section.

The following is the document referred to in the above statement:

WHEREAS, A critical analysis, based upon a classification of physicians by the recent New York State Special Medical Census, when applied to the personnel resident in this State of the Medical Officers' Reserve Corps of the Army, has clearly demonstrated that the volunteer system of recruiting this personnel, now and hitherto in effect, has failed to secure an adequate number of physicians available and desirable for active army medical service; and

WHEREAS, Such analysis has likewise clearly demonstrated that the volunteer system has failed to exclude from this personnel physicians unfit for active military duty, by reason of age, physical disability, family obligations or many dependents; and

WHEREAS, The volunteer system has also failed to exclude from this personnel physicians whose services at home are essential to the public welfare in health departments, hospitals, medical colleges and isolated communities; and

WHEREAS, It has further failed to adjust equitably, in age or geographic or population distribution, the burden of military service upon the medical profession of the United States; and

WHEREAS, It has by these failures caused injury to the individual, to the community, to the medical profession, and to the public; and

WHEREAS, The volunteer system puts an undesirable and embarrassing burden of decision upon those physicians whose services are most needed at home; and

WHEREAS, There exists no provision in the present draft law for drafting physicians as medical officers, but only as private soldiers; and

WHEREAS, The existing general draft law affects only those physicians who are of an age of maximum efficiency as soldiers and fails to affect many of those who are of an age most suitable for medical officers; and

WHEREAS, The justice, wisdom, and effectiveness of the selective draft principle have been recognized by Congress in raising a strong army from our civilian population; and

WHEREAS, We are firmly convinced that a selective draft of physicians for military purposes, based upon a classification similar to that of the New York State Medical Census and designed specifically to exempt those unfit by reason of age, physical disability or many dependents, as well as those necessary for the maintenance of public health, hospital, and community service and medical education, will be alike just to the individual, to the community, and to the Nation, and that it will secure to the medical service of the National defense those best fitted for its uses while it retains at home those most needed in the community; and

WHEREAS, We, the undersigned physicians, graduates of standard medical colleges, and duly licensed to practise medicine in the State of New York, mindful of our duty to our communities and State, as well as to the Nation, are in favor of a selective draft of physicians between the ages of 21 and 45 years, for medical officers, in numbers sufficient for the Nation's military needs, based upon a classification by census, which shall exempt those unfit for military purposes and those necessary for the community at home; and

WHEREAS, We justly claim that such a selective draft of physicians when and if instituted shall and of right ought to exempt graduate physicians, students of medicine, and pre-medical students in the General Draft Law age group from further liability to the provisions of the existing General Draft Law so long as they retain medical status; now therefore

We the undersigned physicians as aforesaid do hereby petition the Congress of the United States for legislation enabling the President to direct the institution of such a classification and to proclaim and order such a selective draft.

Progress of Medical Science.

Boston Medical and Surgical Journal.

August 30, 1917.

1. The Significance of Persistent Pain or Other Symptoms Referred to the Peripheral Nerves. Harold D. Wright.
2. Treatment of the Visceroptotic. Richard F. Chase.
3. Relations of Prenatal and Postnatal Work. Michael M. Davis.

2. Treatment of the Visceroptotic.—Richard F. Chase, some time ago, published observations on 400 women patients with reference to visceral ptosis. Among these he found digestive symptoms in 21 per cent.; backache and abdominal dragging in, respectively, 18 and 24 per cent.; nervous symptoms in 20 per cent.; organic disease outside of the alimentary tract in 19 per cent.; and constipation in 68 per cent. He concluded from this study that treatment of the ptosis itself is indicated in less than 25 per cent. of such cases, because less than that percentage of these patients have symptoms referable to the ptosis. This conclusion, he states, is not in accordance with the popular view. He argues that surgery is rarely required in the treatment of this condition. By far the larger proportion of these cases are benefited or cured by proper dietetic and hygienic treatment. Constipation which occurred in 68 per cent. of this series is curable by dietetic and medicinal treatment. In the care of these cases it is the patient and her entire condition not alone the ptosis that you must treat. In many cases the abdominal support upon which so much dependence is placed by many physicians, does not support. The benefits derived from some supporters are purely mental. The nervous or mental element presented by some of these patients is often the most difficult feature in the entire situation to overcome. Some seem to believe that by overcoming the ptosis, the symptoms will disappear. That such is not the case is proven by the failures of surgery in these cases. The ptosis is quite as often the result as the cause of the general condition of these patients. Hence the treatment must be directed to all of the patient's physical

and mental ills, remembering that the ptosis is often a secondary condition. After treating the patient's physical ills attention must be directed to treatment of her mental ills, her whims, and her phobias.

3. **Relations of Prenatal and Postnatal Work.**—Michael M. Davis makes a comparison of the death rates among infants receiving prenatal care in New York and Boston with the death rate among general cases. During 1914, the death rate of the prenatal cases under one month of age was 17.3 in Boston and 19.5 in New York; in 1915, the death rate of the prenatal cases in Boston was 25.9, in New York 26.0. The death rate for general cases of babies under one month of age in Boston was, in 1914, 45.3; in New York, 36.6. In 1915, the death rate of the general cases was in Boston 38.3; in New York, 35.9. From this it may be seen that the death rate of babies receiving prenatal care is practically the same in New York and Boston. The effect of prenatal care is even more strikingly shown among babies under one year of age, among whom there has been a reduction of 68 per cent. in the mortality in 1914, and of 42 per cent. in 1915. The writer emphasizes the point that prenatal care kills two birds with one stone in that it benefits the mother and the baby also. Logically, prenatal care is the foundation of the campaign against infant mortality, and as the public comes to appreciate its value and far reaching humane significance prenatal work will assume the place that it should. The great difficulty at the present time is that the number of cases reached is far below the number that need to be reached and a selection must also be made of babies needing postnatal care. In making this selection it seems that a nurse who has followed mothers and babies up to two weeks after confinement is in an excellent position to select those babies who need postnatal care. The program for the protection and conservation of infant life must aim to make it possible for every mother to have prenatal nursing service; for every baby who is delicate or who is bottle-fed, or sickly, to be under the skilled supervision of the doctors and nurses of babies' health stations; for every mother who is nursing a baby to have sufficient milk for herself and her child; for every baby who is bottle-fed to have enough and good enough milk at a price which its parents can pay; to enable every mother and father to know how these benefits can be obtained at their expense when they can meet it, or free if they cannot. Such a program is vital for a community in peace time. In war time it is the same, only raised to a higher power.

1. **The Internal Secretions as Related to Tuberculosis in Civil and Military Practice.**—Charles E. de M. Sajous, after discussing the relation of the various glands to tuberculosis, says that on the whole the relationship between the ductless glands and tuberculosis is mainly concerned, so far as our present knowledge permits us to believe, with the defense of the body against infection. When through heredity or local disease these organs are weakened functionally the vitality and defensive powers of the body at large are impaired. By identifying as we can with the addition of knowledge concerning the ductless gland abnormalities the presence of vulnerability to infection, we can arm, as it were, all exposed subjects against the disease. There are phases of the present war which tend to weaken greatly the resisting powers of the troops that previous wars have presented to a comparatively limited degree. These are mainly those due to the vast increase of artillery of large calibre, the intense shell fire, the rapid fire guns, etc., so prolific as causes of shock, terror, etc. The writer recalls that fourteen years ago he emphasized that the pituitary, the posterior lobe of which governed, from his point of view, the functions of the adrenals and thyroid glands, was a sensorium commune through which fright, anger, shock, etc., produced their morbid effects. On the whole it is apparent that this intense functional activity of the ductless glands exerts not only a deleterious effect on the nervous system, but as a result of their inordinate secretive activity these glands suffer from exhaustion. This means that such men are vulnerable to infection of any kind, including tuberculosis. A careful search for the stigmata of endocrine gland insufficiency should form part of the examination of recruits. Especially should the following be noted: *Hypopancreatism*, more or less marked adynamia, mental and physical often mistaken for neurasthenia, accompanied occasionally by gastrointestinal discomfort occurring one or two hours after meals, and perhaps alimentary glycosuria. *Hypoadrenia*, also more or less marked adynamia, but with low arterial tension; weak cardian impulse, slight pallor and sensitiveness to cold, particularly of the extremities. Overworked and underfed men often show these symptoms. *Hyperthyroidia* may be present with the thyroid either atrophied or hypertrophied. In true hypothyroidia the subject may be fat, pudgy, prone to sweat easily, but with skin rather pale than florid. They are usually obtuse and merely grown up backward children, who are unusually liable to tuberculous infection. *Hypoparathyroidia* may be associated with the foregoing or not. The symptoms pointing to this condition are often of a nervous order, usually choreic in character. They are prone to eruptions of various kinds and occasionally to asthma. Hypertrophied thymus is a dangerous condition in a soldier exposed to violent exertion, owing to the possibility of sudden thymic death. All these exposed subjects whether in civil or military practice should have intelligent organotherapeutic treatment.

6. **Studies in Acute Anterior Poliomyelitis.**—George D. Heist, Myer Solis-Cohen, and John A. Kolmer describe the successful isolation and cultivation of an organism which corresponds in every particular with the globoid bodies of Flexner and his co-workers. Their methods were those employed at the Rockefeller Institute. They have succeeded in isolating four strains of the organism. Two were strains secured from glycerinated brain and spinal cord taken from human beings who died of poliomyelitis. One strain came from the fresh brain of a monkey that developed clinical and histological poliomyelitis following the intracerebral injection of a human virus from a patient succumbing to poliomyelitis. The fourth strain came from a poliomyelitic monkey. In all about thirty-five tubes were inoculated with poliomyelitic material and successful growths were demonstrated in five tubes. Growth appeared only under anerobic conditions. The utmost difficulty was experienced in staining the minute organisms. It was found, however, that the microorganisms could be stained easily with a number of the more active stains if previously freed from the ascitic fluid by centrifuging and washing in salt solution. In a satisfactory stain the minute organisms show no particular arrangement. Large masses, clusters, chains and single individuals may be found. The organisms usually, but not invariably, stain violet with the Giemsa stain. In the hands of the authors they have uniformly been decolorized by Gram's method. In addition to the globoid bodies, the writers have in several instances isolated from poliomyelitic material rather large streptococci, occurring in short chains. These streptococci seemed to be of different strains. There seems to be no transition between the globoid bodies and the streptococci. The serums of a large percentage of patients with poliomyelitis gave high opsonic indices with these streptococci, but not with streptococci from non-poliomyelitic sources, nor with staphylococci, diphtheroids, and Gram negative bacilli obtained from poliomyelitic material.

1. Truth About Intraspinal Injections in Treatment of Syphilis of the Nervous System. Bernard Sachs. (MEDICAL RECORD, June 23, 1917, p. 1115.)

2. Intravisceral and Intraabdominal Pressure.—R. C. Coffey states that there is always a variable and indefinite amount of pressure in the peritoneal cavity, known as intraabdominal pressure. This pressure may be greater, but is usually less than the atmospheric pressure. The degree of intraabdominal pressure depends on the variable contents of the abdominal cavity. The variable contents are: (a) extraperitoneal and mesenteric fat; (b) the visceral contents. The visceral contents are liquids and gases and may be intermittently expelled at any time, thus acting as an immediate safety valve for the establishment of an equilibrium and a normal intraabdominal pressure. The extraperitoneal and mesenteric fat is included within the inelastic abdominal wall, and lessens the abdominal cavity in exact proportion to the fat thus included. The law of osmosis by which fluids of different densities pass through an animal membrane and establish an equilibrium, has its counterpart in the relation of intraabdominal and intravisceral pressure. Experiments made by the author make it apparent that intraabdominal fat is deposited under much lower pressure than are the cells of a tumor, pregnant uterus, or ascitic fluid. The deposition of fat within the abdominal cavity does not therefore materially stretch the abdominal wall in a normal person. However, it is sufficient to increase the size of an already existing ventral hernia. This makes it difficult or impossible to replace the hernia at times without removing some of the abdominal contents, such as the great omentum. A patient who has been moderately fat for some reason loses fat; the fat in the abdomen is correspondingly absorbed. The intraabdominal pressure is lowered, and there is a tendency to a gradual atonic dilatation of the hollow viscera with consequent disturbances of digestion, and at times that low state of health ordinarily referred to as asthenia. It is in these cases that rest, forced feeding, and massage are ecective (the Weir Mitchell treatment). Thus it may be said that by strengthening and readjusting the abdominal wall, combined with the deposition of fat within the abdomen, the normal intraabdominal pressure may be restored. In considering the relative degree of pressure in the hollow visceræ themselves, the writer in experimenting with methods for the removal of the head of the pancreas in two stages discovered that the duct which had been transplanted directly into the duodenum at the first operation was invariably found dilated at the time of the second operation. This phenomenon being observed universally, left but one rational conclusion to be drawn, namely, the greater pressure within the intestine was too much when applied to the inside of the bile ducts. The same phenomenon of dilatation was found when the ureter of dogs was implanted into the intestine of dogs. To obviate this difficulty the author makes a submucous transplantation of the bile duct or ureter. Operations on human beings in which this method of transplantation has been employed have been unusually successful.

3. Organic Changes in the Central Nervous System Probably Due to Focal Infection.—George W. Hall. (See MEDICAL RECORD, June 23, 1917, p. 117.)

6. Ovarian Organotherapy.—W. R. Graves, from his personal experience covering a number of years and considerable number of patients, concludes that preparations of the corpus luteum alone are less efficacious therapeutically than are those of the whole ovary. Experiments seem to show that an important part of the ovarian internal secretion is elaborated in the interstitial cells. The interstitial cells correspond to the theca lutein cells of the corpus luteum. The interstitial cells of the ovary are analogous to the testicular interstitial cells of Leydig, which are known to elaborate an internal secretion. Ovarian therapy for its best effectiveness should include at least the product of the interstitial cells. Preparations made of the corpora lutea of pregnancy proved too toxic for practical use. Preparations made from the ovaries of pregnant animals, with exclusion of the corpus luteum, proved superior therapeutically to preparations of whole ovaries of non-pregnant animals that included the corpus luteum. The superiority of the follicular products of pregnancy is explained by the fact that during pregnancy, follicle atresia is especially marked, and is accompanied by a corresponding increase in the interstitial cells.

8. The Foundations of Voice Impairment Resulting from Tonsillectomy.—Elmer L. Kenyon has made a study of the physiology of the soft palate and of the mechanicophysiological importance of the tonsil, based on the careful examination of 161 tonsillectomized throats, and on a study of 30 cases of voice or other disturbance resulting from tonsillectomy. He concludes that unless through the exercise of better technique or of greater skill, the deformities from tonsillectomy can be diminished, tonsillectomy is in a situation which if not alarming is at any rate serious. In removing the tonsillar capsule we take out an important supporting structure on which the normality of the physiological action of the soft palate largely depends. Cases in which operation has been performed, as they exist, show a frightful amount and degree of postoperative deformity dependent in large part on the very principle of the operation. Danger to the speaking voice necessarily lurks in the very nature of the operative conditions, and impairment to the speaking voice is inevitable in an as yet unknown percentage of cases. The danger to the singing voice from stiffness and adhesions begins, theoretically, long before that to the speaking voice. The present situation calls for further intelligent efforts applied to technique and delicacy of procedure and possibly to greater care in lessening postoperative scar tissue. Until the situation is further cleared up, for the surgeon to go on performing indiscriminately tonsillectomies on the throats of adults with singing voices of great beauty or of great importance to their possessors is for him to take risks which the artist himself would not consent to take did he know clearly the situation. The weakness of the present professional attitude in favor of the exclusive employment of the extracapsular operation lies in the fact that no evidence exists which proves that an operation aiming at a clean complete intracapsular lymphoidectomy might not prove to be practically as capable of eliminating infective dangers as the present extracapsular operation. Such an operation would not only be free from serious deformity, but would be altogether a less serious operative procedure. The profession in justice to its scientific aims must turn toward the matter of developing a thorough though relatively conservative operation, which preserves undisturbed the tonsillar capsule.

1. Gunshot Wounds of the Knee Joint. Treatment in a Base Hospital.—J. Campbell and H. H. Wolfenden give full details of a treatment which they have found

to be of great value. Their work covers a period of about two years in a base hospital in France and their conclusions are based on many hundreds of cases. The aim of the treatment in all but the very mildest cases is to obtain complete obliteration of the joint ending in bony ankylosis. The first essential in the treatment of septic infection of the knee joint is drainage and the usual incisions on either side of the patella are utterly inadequate to prevent accumulations, for the pus would have to ascend against gravity to escape from the joint, even though the lateral incisions have been large. The authors have employed several methods but they find that the most effectual way of draining the joint is to make posterior incisions, thereby confirming the value of the method of Major Novis, described in *The Lancet* of July 7, 1917. The authors are entirely opposed to the use of rubber drainage tubes in the joint, holding that the drainage tubes maintain the sepsis and interfere with the closure of the joint, and they view with equal disfavor washing out the cavity, for this procedure also delays or prevents the obliteration of the synovial cavity. The principles of treatment which they rely upon are: first, complete fixation of the joint, and this is obtained by the use of the Thomas knee splint, with fixed extension. The thigh and calf are supported in the splint by sheets of perforated zinc. When these supports are once applied they are never removed if possible, even when an operation has to be performed, and in order that no further infection of the joint should occur, it is recommended that one surgeon only should deal with the cases and do all the dressings himself. The Carrel treatment is employed, the tubes being carried into the innermost recesses of the joint. The wound is dressed with gauze moistened with the hypochlorous solution, and two or three drachms of the solution are injected down each tube at intervals of two hours a day and night with perfect regularity. When this method of treatment was efficiently carried out the infection was effectually counteracted; even from the deeper parts of the wound the invading organisms and their products were washed outwards and no further infection of the joint from without could occur. From the records of his series of cases it appears that the amount of pus under this technique is very small and adhesions form quickly between the bones leading to the obliteration of the joint cavity, and furthermore it is unnecessary to dress the case more than once in twenty-four hours.

3. **Thermalgia (Causalgia).**—John S. B. Stopford reports a number of cases of this distressing condition, which he believes has not received the attention it should because of the misleading name applied to it. He suggests the substitution of the more obvious name, thermalgia. He points out that the condition occurs much more frequently in gunshot injuries of the nerves than in civil injuries, this being due to the frequency of partial division and the excessive formation of scar tissue in the former. From a study of a large number of cases it is clear that thermalgia as generally described is only an extreme type of many median and sciatic injuries and to determine its etiology it is necessary to investigate all cases in which pain is the predominant and constant symptom. The associated symptoms of median and sciatic injuries may vary considerably. From the appearance at operation and microscopic examinations of excised portions of nerve the two constant conditions are partial division of the nerve and intraneural fibrosis. There is also an increased vascularity as evidenced by the color of the nerve and the aggravating oozing which occurs during neurolysis from the divided capillaries. The intense pain may best be explained as due to some interference of vasomotor control. All the conditions point to vasodilatation, but the mechanism by which it is induced is not so evident. Since severe pain is the urgent symptom the object of treatment must be directed toward its relief. Usually only a few of the nerve fibers are severed and the aim must be not only to relieve the pain but also to conserve the undivided fibers. Only operative measures achieve this satisfactorily, and to obtain the best results they must be adopted at the earliest moment. The indications for early operation are the agonizing pain, which wears the patient mentally and physically and may persist for months and so prevent the paralyzed muscles from being treated, and the permanent disabilities motor, sensory, and vascular, which are frequently the result of the progressive fibrosis. The essential factors in successful operative treatment appear to be: (1) Careful separation of all adhesions around the nerve and absolute clearing of all perineural fibrosis. (2) Complete hemostasis to reduce the resultant scar as much as possible. (3) Protection of the nerve at the site of injury to prevent recurrent adhesions. Fat seems to serve this purpose best, since it minimizes the risk of the formation of a thick fibrous sheath around the nerve. Failing to procure fat, it is best to suture the injured muscles so that the raw surfaces are exposed and only undamaged portions are in contact with the nerve. From the author's personal observation it has been proved that this is preferable to substituting any other material for fat. Suture of a few severed fibers is to be avoided on account of the risk of further irritation and recurrence of symptoms, and further, more good functional results occur without it.

5. A Possible Electrocardiographic Sign of Myocardial Change. S. Russell Wells and J. Strickland Goodall.

2. A Reconsideration of the Principles and Methods of Hugh Owen Thomas.—J. Lynn Thomas calls attention to the fact that Hugh Owen Thomas is the author of the treament of delayed union of fractures and diseases of the joints by what is known today as Bier's method, but which was called by its originator "Damming the circulation" (Thomas on "Principles of Treatment of Fractures and Dislocations," p. 29-30, 1866). He reviews Thomas' method of treating fracture of the femur, reducing simple backward dislocations of the ankle joint, setting a Pott's fracture, reducing dislocation of the hip, the aftertreatment of amputations at or above the knee joint, and his diagnostic method for detecting flexion deformities at the hip joint. The writer especially emphasizes the fact which he thinks is not sufficiently realized by the profession, that the amount of force used by Thomas and Robert Jones in the treatment of orthopedic cases is enormous, far greater than that in general use. For example, the force of the pull reducing dislocations of the ankle or of a Pott's deformity after the method described in this paper easily exceeds 300 pound weight. In wrenching a foot a Thomas' wrench 12 inches long and applied in the way that Robert Jones uses it against the hip has enabled the writer without much strain to raise a dead weight of over a quarter of a ton (564 pounds). The strength of the side bars of Thomas' knee splints even for children is at least four times as strong as the aluminum splint used for adults, while Thomas' adult splint will stand more than ten times the force which renders the aluminum rod perfectly useless. By setting a fractured limb Thomas meant that the limb was to be restored to perfect symmetry, that is to say proper alignment and length. In order to do this he used forces running into hundreds of pounds at the time of setting by means of pulleys, levers, and special appliances constructed for the purpose. The writer believes that the vogue of operations for plating fractures and for tenotomy is only a passing fashion, that there will be a return to Thomas' methods, and that the creation by the War Office of military orthopedic centers embodying Thomas' plan of establishing workshops in direct connection with the hospitals is a development full of potentiality for good.

5. A Possible Electrocardiographic Sign of Myocardial Change.—S. Russell Wells and J. Strickland Goodall say that, while modern methods of examination permit surprisingly accurate diagnoses of valvular defects, there has by no means been the same precision in our means of determining the state of the heart muscle. It is not possible as yet to say that we can accurately visualize in any individual case the condition of the myocardium as we can, for instance, that of the aortic valves. The authors have had during the last few years the opportunity of examining several thousand

heart cases and of comparing the clinical findings, and in a large proportion the subsequent histories as well, with the electrocardiograms. As a result of these observations they have become convinced that the height of the second ventricular, or T wave, affords some indication of the efficiency with which the ventricles are functioning. With a view of bringing their opinions in some measure to the proof, it seemed that if they could get cases in which there was clinical evidence of myocardial change, and in which the electrocardiogram showed small or absent second ventricular waves, and if on treatment these waves increased or reappeared in the electrocardiograms concurrently with an improvement in the clinical conditions, it would, to a certain extent, support their contention. Unfortunately myocardial degeneration is not a condition that yields readily to treatment, so that suitable cases for such an observation are by no means common. It seemed, however, that syphilitic myocarditis might afford the required material. They have investigated two cases of syphilitic myocarditis which gave very conclusive proof that absence of the second ventricular wave in the electrocardiogram indicates myocardial change. These curves serve to confirm many others in their possession, and they hope other observers, and above all electrocardiographic observers, will put on record their experiences, not only in syphilitic cases, but also in other forms of myocardial involvement.

La Presse Médicale.

August 2, 1917.

Elimination of Quinine by the Urine.—Jeanselme and Dalimier state that most of the quinine taken for malaria escapes by the kidneys. We do not know how long it remains in the body and the authors sought to determine the point, for after elimination has ceased more of the remedy may be required. A practicable reagent to employ for this purpose is Tanret's iodomercuric solution which throws down all alkaloids in solution. To experiment, the authors exhibited 1 gm. of basic hydrochlorate of quinine by the mouth and by intramuscular and intravenous injection. When injected into a vein the alkaloid appeared at once in the urine, reached its maximum in from 4 to 6 hours, and disappeared at an average time of 27 hours. Given by the two other methods the drug reached the urine in from 15 to 25 minutes. When given by the mouth it disappeared from the urine in 35 hours, but after intramuscular injection whether in solution or oil emulsion it remained in the body for 50 or 60 hours, so that other things being equal this should be the preferred way to give the drug to secure economy of dosage, as far as a single dose is concerned. But when the drug is exhibited in repeated doses all this selection seems to disappear, for if a fixed dose is given daily for 4 days, the drug does not leave the urine for 48 hours, irrespective of the route used. There is, however, this difference, based on the first results, that while by the mouth or the intravenous route a daily dose is necessary, by the intramuscular route a dose every second day will suffice.

Pathogeny and Evolution of Diphtheria.—Danyss sums up our latest acquisitions on these subjects as follows: Diphtheria is a local infectious disease, the antigen being colloidal, soluble, and directly toxic. There is no incubation period. The affinity is wholly for the cells of tissues of ectodermic origin. The antibody is normal, intracellular, and can fix the antigen with overloading. Compounds of antigen and antibody may be immunizing for the cells and the organism if the quantities are equivalent or if there is an excess of antibody; or they may be more or less pathogenic (anaphyiactic) if there is an excess of antigen with fixation of the latter by the cellular antibody in excess. The intravascular reactions involve the formation of neutral, soluble, and directly assimilable or eliminable compounds of the quantities of antigen and antibody (antitoxin) are equivalent or if the latter is in excess. Anaphylaxis under such circumstances will never be produced.

The Oculocardiac Reflex in Wounded Soldiers.—Gautrelet sums up his investigation of this subject as follows: The oculocardiac reflex is clearly exaggerated in the majority of wounded soldiers observed some months after the injury. There is a constancy and special intensity of this symptom in subjects with reflex contractures. An exception is seen if the traumatism is purely osseous. The sympathetic disturbances seen with a positive oculocardiac reflex indicate the presence among wounded soldiers of a nervous disequilibrium in the interest of the autonomous nervous system.

Le Progrès Médical.

August 11, 1917.

The Myotonic Reaction of the Trapezius in Pleuropulmonary Tuberculosis.—Loeper and Codet refer to the classic belief that in tuberculosis some of the muscles of the shoulder girdle undergo atrophy. There is a possibility that such atrophy is the result of myositis or neuritis but it is chiefly of reflex origin and seldom occurs save in the presence of a deep seated lesion of advanced tuberculosis. In an acute process the evolution of the atrophy may be acute. Difficult of recognition the myopathy has no small diagnostic value when present, but naturally only when it is of precocious evolution. The muscles whose fibers run transversely are those in which reduction of size is most readily recognized. Percussion of an affected muscle causes a contraction and the formation of a knot *in situ* which is limited in extent and of short duration. Pinching does not cause contraction but a knot is formed which persists longer than that above mentioned. This nodal formation has been termed myoedema but myotonic reaction is a better term. Under the former designation have been included phenomena seen in nontuberculous affections and it has even been regarded as a cachexia reaction, an infection reaction, etc. It is not claimed to be in any wise peculiar to consumptives and perhaps connotes only a general muscular irritability due to toxemia. The authors write with special reference to a myotonic reaction limited to the trapezius. If the superior border of the latter is pinched while relaxed, using a special technique, a knot becomes apparent both to vision and palpation and persists from 5 to 10 minutes. The reaction should be equal on both sides and inequality implies a pathological condition. Thus in affections of the lung parenchyma, as pneumonia, the reaction is more pronounced on the affected side. In chronic pleuritis with adhesions the reaction appears to be inhibited. But these inequalities are difficult to appreciate *per se*, and electrodiagnosis must be used to render them more obvious. The authors have studied 300 cases of tuberculosis in respect to the myotonic reaction and learned that inequality is of very common occurrence. In infiltration and cavities of the apex the accentuation of the reaction on the affected side is striking. Even special congestion can determine an inequality. As already stated, acute processes cause a specially lively reaction on the affected side. When there are complications of lesions, which often happens, the diagnostic value of the reaction is weakened. The authors assert their belief that in all routine examinations the state of the myotonic reaction of the trapezius should be worth recording.

Il Policlinico.

June 24, 1917.

Rare Case of Rupture of the Aorta.—Soprano reports the following: A soldier reported ill on a morning, accusing vague rheumatic pains. He was admitted to a medical ward and five hours after his first appearance before the regiment surgeon was seen to turn pale and fall. He had died instantaneously. The victim, aged 36, had been robust and cerebral hemorrhage seemed out of the question. A case of cerebrospinal meningitis had recently occurred in the division and this made it advisable to perform a thorough autopsy. The provisional diagnosis, however, was rupture of an aortic aneurysm. The autopsy was made by an expert pathologist who found the encephalon absolutely intact as was also the abdominal cavity. When opened from in front the thorax seemed quite normal save that the pericardial sac was found distended with blood clots. The heart, although compressed by the latter, was entirely natural. The great vessels at their origin were invested with a mufflike formation of blood clots. About 2.5 cm. from the origin of the valvular orifice of the aorta and on its anterior wall was a long tear (3 cm. in length) with

even borders. The vessel wall was quite normal and showed no dilatation. Nowhere was there any suggestion of lues, malaria, or arteriosclerosis. In other words, here was a veritable traumatism of an intact structure with no clue as to its nature. The autopsy diagnosis was "rupture of the aorta with secondary hemopericardium due to a probable traumatic cause and as the sole cause of death." A history was obtained of a fall on the sternum but there was no trace of external injury. The victim had been working at machine rock drilling and was in the habit of supporting the hammer on his chest when it was not in action. For several days before his death he had worked only with a crowbar. During this period he had complained of a stabbing sensation in the cardiac region and it is possible that this was associated with the fall above mentioned in which he may have struck his chest upon a rockpile. The rheumatoid pains for which he had first applied for relief, which seem to have been felt about the chest, suggest a possible angina pectoris due to aortic disease. But such data throw little light on the probable mechanism of the injury. The author knows of but 4 analogous cases in literature. Three factors are believed to be necessary to rupture a healthy aorta, viz., muscular effort, with high intravascular tension and sustained pressure upon the internal wall of the vessel. In one of the 4 cases on record a soldier fell dead on the march after complaining of vague pains in the chest. He had spent the preceding night in an orgy. At autopsy it was found that the ruptured aorta was free from pathological alterations.

July, 1917.

Repair of Perforated Gastric Ulcer with a Free Peritoneal Transplant. Raabe reports a case of gastric ulcer in a man of 45 who was under regulation medical management when a perforation occurred. Laparotomy was performed and the lesion was found on the lesser curvature. Attempts at suture were unsuccessful and a flap 4 cm. x 4 cm. was taken from the peritoneum between the falciforni ligament and the parietal reflection and fixed over the opening with matrass sutures. The infected peritoneal cavity was now disinfected and drained at the lowest angle of the wound. For three weeks patient was nourished with rectal enemata. The first day the Murphy drip was used and thereafter eggs and milk were given by the rectum apparently without attempts at predigestion. From the 23d to 30th day patient was nourished both by rectum and mouth. This prolonged rest of the stomach was doubtless responsible for the success of the transplantation. Importance was also attached to cauterization of the margins of the opening with carbolic acid. After suturing was complete the suture lines were touched with iodine tincture. This operation was performed in August, 1916, and the patient did well until the following May, when he presented symptoms which suggested pyloric obstruction. The final diagnosis after radiography was benign stenosis of that orifice. An operation was performed of pyloric exclusion by retrocolic gastroenterostomy but death occurred from postoperative pneumonia. The anterior margin of the liver, the stomach and part of the transverse colon were adherent to the abdominal wall. The remains of the old defect on the anterior surface could be made out in a mass of scar tissue, with the transplant in place. But a second ulcer was found on the posterior wall of the stomach which showed beginning cancerous involvement under the microscope. During the operation the presence of adhesions had made it necessary to unite the central portion of the stomach to the jejunum where the peritoneal cavity was free.

Acute Leucemia.—An article on this subject by Nicolaysen closes with a summary of differential diagnosis between the acute myelogenous and acute lymphatic forms. The blood picture, when Pappenheim's staining method is used, is usually sufficient. In many cases the diagnosis can be made clinically in association with the application of the criterion of indophenol synthesis. Of three cases reported by the author one appears to have been lymphatic and the other two myelogenous in origin. In the first named, aside from evidences of the blood count, the indophenol test was negative. In one of the myelogenous cases, briefly narrated, there was evidently no room for doubt in the diagnosis, the blood current being unequivocal.

Correspondenz-Blatt für Schweizer Aerzte.

July 21, 1917.

Active or Conservative Treatment of Abortion.—Engler analyzes 170 cases of abortion treated in the Strassburg Gynecological Clinic from April to November, 1916. In all but 10 cases, in which complications were present, active treatment was used, chiefly curettage. Of the 160 cases 100 had no fever at any time, 30 had subfebrile temperatures and 30 actually had fever (38° and above). It is a question whether subfebrile cases should not belong under febrile cases. They often make the impression of sick or infected women and may have premonitory chills. A good rule is to regard all fever-free patients as candidates for active treatment. The average sojourn of this class in the hospital was 5 or 6 days. In both the subfebrile and febrile classes practically all cases ran a mild course and there was no mortality. In fact, but 2 of the 160 cases could be regarded (aside from the temperature) as really ill. The total average sojourn for the 160 patients was but 7 days. Naturally curettage is doubly urgent in the feverish and febrile cases. Bacteriological studies were made in 120 cases and hemolytic streptococci found in 15. In 38 others anhemolytic streptococci were present while in 28 there was an abundance of mixed cultures. Some 25 cases may be regarded as sterile. Comparison of the bacteriological finds in the three types of cases is not instructive. The nonfebrile cases showed as many pathogenic germs as the febrile—perhaps more, for a third of the febrile cases gave negative finds. It is supposed that in such cases the patient enjoys an immunity.

Significance of the Cuti-reaction after Tuberculin Inoculation for the Therapy and Prophylaxis of Tuberculosis.—Lanz sums up his extensive study as follows: Repeated cutaneous inoculation with tuberculin exert—like the injections of the same—a curative effect, the tuberculin being built down to harmless substances, protective antebodies are formed, the system is detoxicated. These processes come about through reactive inflammations in the superficies of the skin as a result of which diseased foci are spared and an injurious general reaction is avoided. Hence cutaneous reactions are superior to injections for the latter are associated with a hemic reaction. Sahli's procedure with groups of punctures is superior to others provided the dosage and increase are proper, because the conditions favor a larger dose of tuberculin. The cutaneous method is readily carried out in the case of the curative and symptomatic treatment of mild and severe cases respectively and is also adapted to the prophylactic treatment of those who have been exposed or who have latent foci. Hence it is possible to use it in the group treatment of the public under certain conditions. The services of several practitioners may be necessary and the group should be treated over a considerable interval. The dietetic-hygienic treatment should be maintained with its customary rigor.

Whole Bread.—According to Lepinay a bread made from whole grains has been used in Paris for the past twenty-five years. Externally it is black and on section yellow-brown. It is palatable and known chiefly as a dietetic bread. It ought to be cheaper than white bread, but for some reason it is dearer. There are whole wheat, whole barley, and whole oat breads of this character, and similar loaves may be made of rice and buckwheat. It is possible to make mixtures which appeal to individual tastes and requirements.—*La Presse Médicale.*

Alcohol and the Needle-Threading Test.—Tössermann abstained from alcohol for two weeks and then for a second period of the same length drank every evening at 11 P. M. 100 c.c. of a 25 per cent. solution of alcohol (about equal to 3 ounces of 100 proof whiskey). At the end of each period he tested his ability to thread 200 No. 6 needles according to a special technique, and computing by time units found his efficiency had been diminished about 10 per cent. as a result of the alcohol ingestion.—*Annali d'Igiene.*

Book Reviews.

SCIENCE AND LEARNING IN FRANCE, With a Survey of Opportunities for American Students in French Universities. An Appreciation by American Scholars. Price $1.50. Published by the Society for American Fellowships in French Universities, 1917. Sales Agents: A. C. McClurg & Co., Chicago.

THE scientific and literary world not only of France but of this country as well owes a debt of gratitude to the Society for American Fellowships in French Universities for conceiving and carrying to execution, under the capable editorship of Prof. John H. Wigmore of Northwestern University, Chicago, the idea embodied in this handsome volume. The publication of the volume is timely now that Germany is closed to students and is not likely to be sought by those of the Allied nations for many years after her defeat. Foreign study is, however, desirable if only for giving a new direction to thought, and it is a praiseworthy undertaking to make known to the many what has long been known to the few, that France holds out opportunities for study in some respects far more to be prized than those formerly so eagerly sought in Germany. That America has not appreciated this sooner is largely the fault of France herself; her spirit of chauvinism, forced on her perhaps in a measure by the overbearing insolence of the Teutonic victors, for many years repelled those who would have visited her universities gladly had they felt they were welcome. Now, however, the University regulations which practically barred out Americans and other foreigners have been removed, and with them, helped on no doubt by the new feeling of brotherhood engendered by the war, has disappeared the chauvinistic spirit that, even more than the University regulations, chilled the ardor of those who admired and loved France and would gladly have studied at the feet of her masters.

The aim of this book is "to put before the American public the contributions of France in all fields of scientific knowledge, and to show her status in the forefront of the world's progress; and, in addition, to furnish to American University students all information bearing on graduate work in France." There are twenty-two chapters dealing with Anthropology, Archæology, and the History of Art, Astronomy, Botany and Agriculture, Chemistry, and the other divisions of literature, science, and art. The introduction comprises two essays on "The Mind of France," by Emeritus President Charles W. Eliot of Harvard, and "The Intellectual Inspiration of Paris," by George Ellery Hale, foreign secretary of the National Academy of Sciences. The three appendices contain much information of a practical character for intending students in French institutions of learning. The section dealing with Medicine is naturally the one that appeals especially to physicians. It comprises six chapters relating to Physiology, Neurology, Internal Medicine, Surgery, and Pathology, with an interesting Introductory Survey by Dr. T. C. Janeway. The other contributors to this section are Drs. William H. Howell, Hugh T. Patrick, Morton Prince, W. S. Thayer, A. D. Bevan, D. B. Phemister, and F. P. Gay. The reader who has been wont to regard the whole of medical science as "made in Germany" will be properly oriented as to the important contributions to all branches of medicine made by Frenchmen. Throughout the book are many portraits of leaders in science, art, and literature in France.

A perusal of this volume leaves one with a feeling of intense gratitude to the armies of France whose valor kept out of Paris the barbarian hordes which had destroyed the University of Louvain and burned or stolen the books and manuscripts in its priceless library, shelled the Cathedral of Rheims, and wrecked so many other matchless monuments of civilization. One shudders to think of the libraries, museums, and art galleries of Paris given over to the destruction and defilement that follow everywhere the incursions of Kultur.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Twenty-seventh session. Held at the Laurel House, Lakewood, N. J., May 24, 25, and 26, 1915. Edited by LINNAEUS EDFORD LA FÄTRA M.D. Volume XXVII.

THIS volume lives up to the reputation already so well established by the previous ones from this Society. A study of the names of the authors of the articles presented as well as the list of members brings an appreciation of the advances made in pediatrics since the foundation of the Society in 1888. How hard these specialists have worked to develop not only among themselves but also among the general practitioners, a scientific understanding of the body of the child! How long will it be before they wisely decide to put forth as much effort in the understanding of the mental processes which control to rather an amazing extent the physical conditions of the growing boy and girl in a world so completely, so typically all their own?

PRACTICAL DIETETICS WITH REFERENCE TO DIET IN DISEASE. By ALIDA FRANCES PATTEE, Graduate, Department of Household Arts, State Normal School, Framingham, Mass.; Late Instructor in Dietetics, Bellevue Training School for Nurses, Bellevue Hospital, New York City; Former Instructor at Mount Sinai, Hahneman and the Flower Hospital Training School for Nurses, New York City; Lakeside, St. Mary's, Trinity, and Wisconsin Training School for Nurses, Milwaukee, Wis.; St. Joseph's Hospital, Chicago, Ill.; St. Vincent de Paul Hospital, Brockville, Ontario, Canada. Tenth Edition, Revised and Enlarged. Price, $1.50. Mount Vernon, N. Y.: A. F. Pattee, 1916.

ONE studies carefully the seventh, eighth, and ninth editions of books on diseases of the stomach with a sense of bewilderment at the almost hopeless increase in the number of stomach conditions recognized more completely during the past ten to twenty years. Then one picks up a book on dietetics to find it has followed in the footsteps of the books on gastric conditions, bringing up in an almost equal number of editions. What is wrong? Is the race to become one of chronic dyspepsia with an eighth edition of Diseases of the Stomach in one hand, and a sixth edition of Practical Dietetics in the other? Cannot the Practical Dietetics quiet sufficiently the fears of the Diseases of the Stomach, or will the Diseases of the Stomach finally submerge the efforts of the dietetic volumes?

If a brave fight is to be made for healthful living through proper feeding in sickness and disease, then this book of Miss Pattee's well deserves to have lived so wholesomely through six editions. It contains the State Board Examination Questions on dietetics of many States, then proceeds to the principles of nutrition and food preparation. Diets for almost all types of diseases are given; under special diets are given those needed during motherhood, infant feeding, the feeding of young children and adolescents, diet for the sedentary, and ending in a most important, but little recognized dietary field, that of proper food for the aged. Recipes galore are given, and explanations are so clearly given that it does not seem possible that anyone could possibly misinterpret the directions.

The author in her chapter on infant feeding has frankly acknowledged her indebtedness to the work and investigation of several pediatrists, namely, Holt, Shaw, Grulee, and Ladd. She has also expressed her appreciation of assistance received from other medical sources. The dietary routine of many different hospitals is included, naturally, since the author has had such a wide range of experience in teaching in the hospitals of this country and Canada. The book is attractively bound in the blue and white striped muslin used in the making of nurses' uniforms in many hospitals.

THE INTENSIVE TREATMENT OF SYPHILIS AND LOCOMOTOR ATAXIA BY AACHEN METHODS. By REGINALD HAYES, M.R.C.S., etc. Second Edition, Revised. Price, 3s. 6d. London: Baillière, Tindall & Cox, 1917.

BEFORE discarding entirely the older methods of treating syphilis in our enthusiasm for the arsenical preparations it would be well if this handy little volume were consulted. It discusses the mercury inunction, given by trained rubbers and supplemented by sulphur water, both externally and internally, the latter with the idea of forming a soluble sulphide of mercury in the body. This is the treatment as given at Aachen, but the writer is of the opinion that it can be carried out satisfactorily at home, which is interesting in view of the present inaccessibility of Aachen. The book is well written and the illustrations are good.

Food Poisoning. By Edwin Oakes Jordan, Chairman of the Department of Hygiene and Bacteriology, The University of Chicago. Price $1.00 net, postage extra; weight 14 oz. Chicago: The University of Chicago Press.

According to the announcement made in the front of the book, this especial Science Series "owes its origin to a feeling that there should be a medium of publication occupying a position between the technical journals with their short articles and the elaborate treatises which attempt to cover several or all aspects of a wide field. . . . The volumes . . . will present the complete results of an experiment or series of investigations which previously have appeared only in scattered articles, if published at all. On the other hand, they will differ from detailed treatises by confining themselves to specific problems of current interest, and in presenting the subject in as summary a manner and with as little technical detail as is consistent with sound method."

This states exactly what is the matter with this short member of the series. The book is a collection of the newest thought on food poisoning and there is, so far as can be ascertained, no original work incorporated by the author. What is written is well stated, but like so many other attempts that have been made to present scientific knowledge in a popular style, it fails of its purpose. No professional reader would need it, for all of the abstracts have been taken from the journals usually read by the medical and allied professions; as for the nonscientific reader, he would be stranded in a maze of to him unintelligible words. For instance, on page 35, in referring to the presence of benzoic acid in food the author states that "in point of fact, substances present in many ordinary foodstuffs are converted within the human body first into benzoic acid and then into hippuric acid." Turning the page, he refers to a quotation from Folin with reference to the fact that benzoic acid in the system or put there through even unadulterated food, "might be deleterious to health except for the saving hippuric acid forming process." No attempt is made to explain to the reader what this "saving process" is, and even a professional reader would have to brush up his organic chemistry of long ago in order to have a satisfying knowledge from his hour's reading.

The author has no doubt done the best he could in the space allowed him, but it is a pity that such a capable editorial committee as controls this series could not allow a few more pages in order that the book could truly meet the attainment of its purpose, simplicity and clearness as well as brevity, which it at present most certainly lacks.

Mechanisms of Character Formation. An Introduction to Psychoanalysis. By William A. White, M.D. Price $1.75. New York: The Macmillan Company, 1916.

Psychology, perhaps more than many of its sister sciences, has of late years received a tremendous impetus and awakening. This is especially true in its association with the field of medicine, where physicians have been made to realize the value of its employment in the treatment of the mental as well as the physical sides of many so-called abnormal conditions. However much many members of the medical profession may agree or disagree with Freud in his basic facts and theories regarding the processes of psychoanalysis, they are compelled to admit that he has aroused the thinking physician from a trancelike condition as to his responsibility toward his patient. Rather roughly and with a sense of immediate need and advantages of the employment of psychology, Freud has shown that in so many cases not typically medical or surgical there is required a deeper, sounder knowledge of the individual. Not the surface man that the body and ordinary mental processes outline for examination in health and disease has he studied, but that submerged, elusive, unknown self, which, as has proved, governs unconsciously to an alarming extent the attitude and actions of the personality in health, and so much more so when abnormally balanced by fear through disease.

Freud and his theories are not easily understood, even by the followers who so faithfully out-Freud the master. It is not to be expected, therefore, that the average non-psychic, everyday physician can understand or accept so radical an upset of his smugly arranged bases for life, which have carried the most of the profession so safely to port in stormy seas. Freud may be right or he may be wrong, but he has at least accomplished one or two good results—a demonstration of how little is really known about the psychical life of the individual, and a merry war of controversy as to the correctness of the tenets heretofore accepted in psychology together with a controversy over the sweep of the entire Freudian scheme of human life. This controversy has brought forth much literature on the subject. Much has been published which has been almost unintelligible even after considerable study on the part of discerning physicians. This too has been recognized by some of the Freudian adherents, and efforts to elucidate the Freudian concepts have been made. Among these publications is this volume on the Mechanisms of Character Formations offered by White which forms a steppingstone from the old psychology up to the newer field opened up by Freud. The author in as simple words as can possibly be used explains the various terms, symbols, and concepts which form the basis of this new approach to a clearer understanding of humanity. He begins with the genetic approach to the problem of consciousness carries us through the unconscious with its conflict through the libido which seems to be the great stumbling block for many minds, on up to the will and the outcome of the conflict. The book is written with such a sincerity of spirit, such a definiteness of purpose, and with such a subtle charm that whether one is in harmony with the subject matter presented or otherwise controlled, there is no doubt but that the beauty of soul unconsciously imparted, together with the straightforwardness of the attack made on the material offered, cannot help but put the reader in a more tolerant, honest frame of mind and heart toward this new method of comprehension of one's fellow men.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia, assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. June 1, 1917. Price, $6.00 per annum. Philadelphia and New York: Lea & Febiger.

The June number of Progressive Medicine contains chapters on Hernia, by W. B. Coley; Surgery of the Abdomen, Exclusive of Hernia, by J. C. A. Gerster; Gynecology, by J. G. Clark; Diseases of the Blood, Diathetic and Metabolic Diseases, Diseases of the Thyroid Gland, Spleen, Nutrition, and the Lymphatic System, by A. Stengel, and Ophthalmology, by E. Jackson. This work is now too well known to need any detailed comment; but we would draw the attention of our readers to Doctor Clark's discussion on the cancer problem, which is always a feature of the June number.

State Board Questions and Answers. By R. Max Goepp, M.D., Professor of Clinical Medicine at the Philadelphia Polyclinic; Assistant Professor of Clinical Medicine, Jefferson Medical College; Assistant Visiting Physician to the Philadelphia General Hospital. Fourth edition, thoroughly revised. Price, $4.25 net. Philadelphia and London: W. B. Saunders Company. 1917.

Previous editions of this work have been noticed in these columns, and what was said on these former occasions will apply to the present edition. Many of the mistakes to which attention has been drawn are still perpetuated. We still read in the pages of this book that the blood is carried by the inferior vena cava to the left auricle; boron is still said to be one of the constituent elements of the human body; a poison is still said to be any substance producing deleterious effects upon the animal organism; the question on the distribution and branches of the middle meningeal artery is still inadequately answered. All of these errors and others too have persisted from the first edition. We would again repeat that "the value of a work of this sort depends upon its accuracy and not upon its size; and the only students who could use the book with safety are those who do not require such assistance."

Society Reports.

REPORT ON POLIOMYELITIS, WITH ESPECIAL REFERENCE TO THE EPIDEMIC OF 1916,

OF THE JOINT COMMITTEE REPRESENTING
THE COMMITTEE OF PUBLIC HEALTH OF THE NEW YORK ACADEMY OF MEDICINE

AND

THE NEW YORK NEUROLOGICAL SOCIETY

MEMBERS OF THE COMMITTEE: Dr. Charles L. Dana, chairman; Dr. Walter Timme, secretary; Dr. Frederick Tilney, Dr. Nathan E. Brill, Dr. Louis Casamajor, Dr. J. Ramsay Hunt, Dr. William M. Leszynsky, Dr. Philip Van Ingen, Dr. Herbert Wilcox.

WITNESSES. The following gentlemen appeared as witnesses before the committee: Dr. Philip Van Ingen, attending pediatrist Roosevelt Hospital, attending physician Willard Parker Hospital; Dr. Herman Schwarz, adj., attending physician to Children's Service, Mt. Sinai Hospital; Dr. H. M. Amoss, Rockefeller Institute, Research Department; Dr. George Draper, associate visiting physician Presbyterian Hospital, attending physician New York Orthopedic Hospital, Associate in Medicine at College of Physicians and Surgeons; Dr. C. W. Berry, Institution Inspector in Brooklyn; Dr. B. H. Waters, Director of the Bureau of Preventable Diseases of the Board of Health, New York Health Department, visiting physician Riverside Hospital; Dr. John A. Smith, Diagnostician to Board of Health in Brooklyn; Dr. J. C. Roper, associate visiting physician New York Hospital; Dr. O. M. Schloss, attending pediatrist of Bellevue Hospital; Dr. A. Zingher, assistant director in the Research Laboratory, Department of Health; Dr. S. J. Meltzer, head of the Department of Physiology and Pharmacology of the Rockefeller Institute; Dr. Haven Emerson, Commissioner of Health of New York City; Dr. Robert J. Wilson, Director of Bureau of Hospitals, New York City; Dr. B. F. Knause, Borough Chief of Brooklyn.

Object and Method of the Investigation.—The object of the committee was to make what might be called a dynamic study of the situation regarding poliomyelitis in order to find out what has been added to our knowledge of this disease through the studies and experience of the past year, both in clinical fields and in the laboratory. We have not undertaken to make any elaborate analysis of recorded observations and statistics. This work has been done by the Health Department of the city and already a publication containing such statistical reports has been prepared.

We were very fortunate in being able to secure the active and willing co-operation of the best experts of the city in all the fields of inquiry in which we were interested. These gentlemen presented to us no set papers or formal statements, but were good enough to reply to the inquiries that were made of them and to the cross-questioning which followed. The result has been a mass of critically discussed information which we have summarized under the following headings:

1. Bacteriology and Pathogenesis.
2. Immunity and Relative Infectivity.
3. Communicability.
4. Prevention of Spread; Hospitalization and Quarantine.
5. Early Diagnosis.
6. Treatment of the Acute Stage and Prophylaxis.

Bacteriology and Pathogenesis.—The microorganism described by Flexner and Noguchi in 1913 as the "globoid bodies" seems to bear a definite relation to epidemic poliomyelitis. These bodies are obtained in culture with great difficulty. While a variety of ordinary bacteria, easily cultivatable, have been obtained by various workers, the globoid bodies represent a peculiar species and thus far alone have sufficed to produce typical poliomyelitis in monkeys by intracerebral inoculation. In general they fulfil Koch's law of causation; they have not been detected in lesions or conditions other than poliomyelitis; they have reproduced the disease experimentally in monkeys, and they have been recovered from lesions thus produced. No other theory concerning the microbe origin of the disease has been generally accepted, although certain strains of streptococci have been described and claimed to be experimentally capable of producing poliomyelitis. Some evidence sustains this contention. On the other hand, there are certain experimental facts which seem to argue against it.

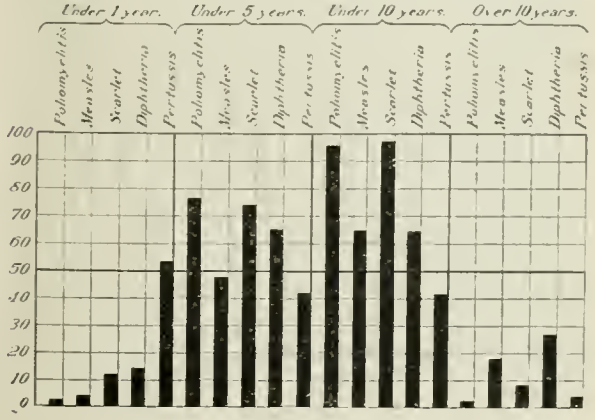
Immunity and Relative Infectivity.—It seems determined that there is a very considerable natural (or acquired) immunity to infantile paralysis. Thus infants under six months of age and most adults have a low susceptibility to the disease. The period of greatest susceptibility is during the third and fourth years. After the seventh year natural immunity seems to be rapidly acquired. The largest reports of cases are of those in the first ten years of life. That the age immunity in poliomyelitis as compared to that of other acute infectious diseases, such as measles, scarlet fever, diphtheria and pertussis is practically identical was shown in the epidemics in Sweden in 1887 and 1889, in Goteberg in 1905, and New York in 1907 and 1916. Ninety per cent. of the cases occurred before the fifth year, and 96 per cent. during the first decade. The epidemic in Sweden in 1905 showed quite a different age-distribution of the disease, as only 17 per cent. occurred during the first three years, 21 per cent. occurring after fifteen years of age, and there was an even distribution of the disease throughout the later years of life. There are rare instances of the disease occurring during the first six months, and very few in the first year of life. The latter half of the second year seems to be the period of greatest susceptibility. The low incidence of poliomyelitis during the first year corresponds closely with that of measles, scarlet fever and diphtheria. In the case of pertussis the incidence is quite different, as one-half of the cases of whooping cough occur during the first two years of life.

The period of greatest susceptibility, that is, from the second to the fifth year, in poliomyelitis again corresponds fairly well with that of measles, very closely to that of scarlet fever, and as compared with pertussis, although the latter is more common in the earlier years of life, the period of greatest susceptibility ceases at about the same time as that of poliomyelitis. In later life the increasing immunity to poliomyelitis seems to go hand in hand with that of measles, scarlet fever, diphtheria and pertussis. The disease incidence decreases quite uniformly in them all, evidencing the steady increase in natural immunity after the tenth year. These facts seemed to indicate that the natural immunity to poliomyelitis is not due to a great prevalence of abortive and unrecognized attacks. It is more likely that this immunity is of the same nature as the natural immunity against diphtheria, scarlatina, etc.

CASES PER 1000 INHABITANTS

	1915	1916
Measles	6.98	3.86
Diphtheria	2.79	2.41
Scarlet fever	1.81	1.04
Pertussis	1.24	1.33
Poliomyelitis	.02	1.61

Age-incidence of poliomyelitis compared with certain other acute infectious diseases in childhood:



Communicability and Contagion.—Poliomyelitis is a communicable disease. It is is mediately contagious, and slightly immediately or personally contagious. This slight personal contagiousness of the disease seems from the facts brought out in the last year's epidemic a thing to be strongly emphasized.

If the Committee's interpretation is wrong, it will have to be shown to be so by further and more careful studies of this phase of the question. Our views are based on the facts given in detail by Dr. Tilney in the appendix. Some of these data are:

1. That only a small percentage of the cases have been shown to have arisen from personal contagion, and in many of these there is not so much proof as inference.

2. That the great mass of the cases arise without any history of personal contagion.

3. That multiple or family cases make up only about 3 per cent., and in more than half of these the members of the family were attacked at about the same time, or not sequentially.

4. That uninfected and healthy children placed in wards containing infected cases do not take the disease.

5. That in an epidemic time (summer of 1916) in institutions caring for children and offering a fair mark for the disease there was no infection expect in a few instances. That in day nurseries in New York City, babies brought from their homes for the day and taken back at night, were not infected.

6. That in urban and rural populations, the number of cases per 1000 is greater in uncrowded country districts than in the crowded city.

7. That the small number of cases of personal contagion is not explained on a theory of very high prevalence of natural immunity.

On the other hand, there are cases which show as plainly as clinical evidence can show, that personal or immediate contagion may occur. Although it is slight and the immunity rate is high, yet its existence must at present be reckoned with. We only wish to emphasize its small absolute importance, and to urge against burdensome quarantine restrictions based on views of its importance.

An infected person, however, can probably communicate the infectious organism to certain agencies, thus making these agencies carriers of the disease. These carriers may be human beings or certain of the lower animals, insects, food, dust, and dirt. No insect or animal has been positively identified as the ordinary and active carrier in the spread of the disease, and there is not as yet any practical method to detect a human carrier.

The evidence that the germs are carried about by agencies which spread the disease, is based on many clinical and experimental observations. It seems possible that certain changes occur in the infecting organisms which make it possible for the carrier to transmit the disease while the infected person does not.

Prophylaxis; Hospitalization and Quarantine.—Experience shows that quarantine so far has never stamped out an epidemic, or affected its progress. This may be because it controls the infected person too late and does not effectively control the carriers. However, as the disease is infectious and is spread through agencies starting probably from the patient, it is wise at this stage of our knowledge to quarantine the patient, and to do this as early as possible. The efficacy of interstate quarantine, as well as of the quarantine of one town or one community against another, has not been demonstrated. On this account such quarantine seems ill-advised because of its harmful effects upon the public state of mind. The public should know that the disease spreads by agencies which we do not now recognize.

The quarantine instructions recommended by the Committee of Conference of State and Provincial Boards of Health of North America should be carefully followed. It has seemed wise that physicians, nurses, and members of the family who come in contact with the child should use the gown and protection to the head regularly required in hospitals for contagious diseases. Children are best protected by having them placed in a region free from the epidemic, or by having them live the cleanly, regular life of a well ordered hospital ward. Such a life would mean:

1. *Diet*, consisting of: Simple well cooked food suitable to the age of the child. Absolutely pure milk. Plenty of boiled or pure water. Stewed fruits and baked apples. No fresh fruits. Thoroughly cooked fresh vegetables, except corn, cabbage, turnips and tomatoes. No candies or other confections except in sealed packages. No ice cream or beverages from public venders. (In so far as possible, home preparation of all articles of food is particularly recommended.)

2. *General Hygiene:* Daily sponge or tub bath. Light washable clothing, frequently changed. Careful attention to the bowels. Avoidance of boisterous or over-strenuous play. Rest and quiet during the middle of the day. Avoidance of undue exposure to the sun. Proper number of hours for sleep according to age of the child. Insistence of routine in this particular. Separate bed for each child. Individual towels, wash cloths, soap, etc. In summer, especially during an epidemic, children should use public conveyances as little as possible, and avoid all public places.

3. *Sanitation:* Thorough cleanliness of the home, including avoidance of scattering dust during sweeping, careful cleansing of floors, woodwork, bedding and clothing. All windows should be screened. Flies should be kept out of all rooms, and especially prevented from gathering about food. Refuse containers must be kept covered, and regularly emptied. The necessity of personal cleanliness should be impressed upon the children.

The duration of the quarantine has not been entirely agreed upon. Hospitalization is recommended for cases in which the following home conditions cannot be fulfilled: (1) The regular attendance of a private physician, (2) a separate room for patient and attendant, (3) a separate toilet for the family of the patient, (4) cooperation in the quarantine regulations.

Hospitalization has proved advantageous to children suffering from poliomyelitis. Furthermore, it seems to be definitely shown that the disease is not transmitted from sick poliomyelitis cases to other sick children in hospitals, and that it is perfectly safe to send cases of infantile paralysis into a general hospital where there are other children without there being any danger of communicating the disease. Poliomyelitis rarely invades hospitals. It did not last summer. These facts appear to be due partly to the slight communicability of the disease—perhaps to the fact that the contagiousness, as in measles, is for the most part in the early stages of the disease, partly to the fact that, in hospitals especially, the methods of care for the sick prevent the transference of the disease from one patient to another. It therefore seems advisable that in any family where the disease breaks out the same methods of care for the sick in the way of contacts, of cleanliness and care of the discharges be used as are followed in the cases of contagious disease in hospitals.

Early Diagnosis.—There is no absolute and infallible means of diagnosis of this disease, but during an epidemic the presence of an acute illness with the accepted symptoms of meningeal irritation, and accompanied by an increase in the cells and pressure of the cerebrospinal fluid, make early diagnosis sufficiently easy. By some authorities the disease is thought to have a definite prodromal period which presents definite signs. These signs may last for a few hours or several days. During this time the child becomes irritable, complains of headache and loss of appetite. and slightly immediately or personally contagious. This clinical picture presents the usual features of an acute gastro-intestinal disturbance. A slight febrile reaction is often noted, varying from 99-101°. The child seems dull and listless. If the infection is particularly virulent in this period, the eye becomes bright and glassy. There is also a puffiness above and below the eye-lids; drowsiness and irritability alternate while the temperature often rises to 102°. Constipation is the rule. Another sign to which much importance is attached is the "stiff spine." This is a muscular condition in which the muscles of the back voluntarily contract whenever the attempt is made to move the child, even to a slight degree. During this prodromal period, the spinal fluid usually presents nothing abnormal beyond a slight increase in pressure. In suspected cases, however, lumbar puncture should be re-

peated every 8-12 hours. There may be no increase in the cells or in the globulin of the spinal fluid at this time.

All of the acute symptoms of the prodromal phase may disappear, and the patient seem to be in normal health for several days. Then there occurs an apparent recrudescence of the infection and paralysis develops. On the other hand, the child may not entirely recover from the acute symptoms and may remain ill for several days. At the end of this time, the paralytic symptoms develop. Immediately before the onset of the paralysis the stiffness of the spine becomes more pronounced. It is at this time that the spinal fluid first gives veritable signs of meningeal involvement. This is shown by the marked increase in the cells as well as an increase in the globulin. The number of cells, and the amount of globulin found in the fluid during this period does not furnish any definite basis for prognosis in regard to the severity or course of the disease. The blood changes are practically without significance. The marked change in cell and globulin content of the spinal fluid noted in the paralytic stage is taken as evidence of infection of the central nervous system. Cases in which the infection is limited to tissues other than those of the brain and cord constitute the group which manifests no neurological symptoms. These have been called the "abortive group," but it would seem more correct to designate them as cases without paralyses in contrast to the even better known group in which the nervous system is involved, i.e., poliomyelitis with paralysis. The prodromal period is difficult to detect except during an epidemic.

Treatment of the Acute Stage and Prophylaxis.—With regard to the treatment of the disease in its acute stage we have received data as to the use of serums—the serums of immunized patients. There is some evidence that the use of such serums does good when it is used in the preparalytic stage or at the very earliest stage of the disease. Injections of convalescent serum, 15 to 20 cc. intraspinally alone, or in addition to 30 cc. intravenously and subcutaneously have been recommended. Normal horse serum has also been recommended, but its use does not seem to be advisable. Most of those who have employed serum of one kind or another are conservative in their statements. They make no claim that they have found a means by which to cope with the disease successfully. It is their belief that since this means of therapy is the only one which has a rational basis and does no injury to the patient, it is worthy of a trial, and should be used in all cases where the diagnosis may be made prior to the paralysis. The statistics of their observations while extremely suggestive, fail to bring conviction that a specific remedy for this disease has been discovered. The intraspinal administration of adrenalin has been recommended but is still in the experimental stage. Tonsillectomy, advised by some, is endorsed by few. Lumbar puncture has been of use where there is increase of pressure and in certain cases multiple puncture at twelve-hour intervals has been helpful. In respiratory difficulties morphine may be given to induce a minimum of respiration, and oxygen may be administered by intratracheal insufflation.

No method of making children immune to the disease, or of testing out the question of their immunity by something analogous to a Schick test has been discovered. The ordinary methods of treating acute attacks have been already widely published, and nothing new has been contributed.

Prophylactic measures such as spraying of the throat and nose and gargling are deemed not only unavailing, but objectionable, if not injurious, in infants. They may tend to make the mucous membrane of the upper-air passages more pervious to the microorganism of the disease.

Acknowledgments of the Committee.—The Joint Committee wishes to express its deep appreciation for the courtesy and cooperation of the following gentlemen, whose earnest efforts in the interest of our knowledge concerning poliomyelitis have furnished the basis of this report; namely, Drs. Haven Emerson, Philip Van Ingen, Herman Schwarz, H. L. Amoss, George Draper, C. W. Berry, B. H. Waters, J. A Smith, J. C Roper, O. M. Schloss, A. Zingher, S. J. Meltzer, R. J. Wilson and B. F. Knause. We are also much indebted to Dr T. H. Weisenberg of Philadelphia for several important contributions.

Appendix to the Report

The following appendix is attached to the report since it gives the statistical basis for the conclusions of the committee concerning the contagiousness of the disease.

Studies of other epidemics as well as the epidemic of 1916 were made under the following headings:

I. Analysis of District Distribution of the Disease.
II. Institutional Incidence in Charitable Institutions.
III. Incidence and Isolated Communities.
IV. Multiple Incidence.
V. Incidence of Isolated Cases.
VI. Other Possibilities than those of Direct Personal Contact.

I. *Analysis of District Distribution of Disease.*—In crowded city districts incidence 1-1000 or 0.1 per cent. In Richmond, a rural or suburban incidence, 3-1000 or 0.3 per cent., that is, triple the incidence in city areas. The opportunities are certainly better in the city for contact, but the incidence is higher in rural districts; hence some element other than contact should be considered. This element is more prevalent, however, in rural districts. This strongly suggests that spread depends upon some population other than human. Cats and rats are more common in the country.

II. *Institutional Incidence.*—In certain institutions which care for children, cases of poliomyelitis developed during the epidemic. They are as follows:

CHILDREN'S HOMES AND NURSERIES

1. *Sea Breeze Home, Coney Island*

1. Number of inmates 2087
2. Total number of poliomyelitis cases..... 2
3. Total number developed in hospital..... 2
4. Personal contact with other poliomyelitis cases .....Not proved
5. Day of development after admittance..... .....Case (a) after 1 day, case (b) after 5 days
6. Development occurring within two weeks incubation after admittance.....Both cases
7. Infected before or after hospitalization..... .....Both cases before
8. Occurrence before or after quarantine was established .....Before
9. Contact with possible carriers.....Not proved

2. *New York Foundling Hospital*

1. Number of inmates..... 650
2. Total number of poliomyelitis cases..... 4
3. Total number developed in hospital..... 4
4. Personal contact with other poliomyelitis cases .....3 (not proved) 1 (adjacent bed)
5. Day of development after admittance..... .....1 (7th day) 3 (14th day)
6. Development occurring within 2 weeks' incubation after admittance. All except 1 case developed in longer than incubation period.
7. Infected before or after hospitalization..... .....1 before, 3 after
8. Occurrence before or after quarantine was established .....All before
9. Contact with possible carriers.....Not proved

3. *Angel Guardian Home*

1. Number of inmates 600
2. Total number of poliomyelitis cases..... 1
3. Total number developed in hospital..... 1
4. Personal contact with other poliomyelitis cases .....Not proved
5. Day of development after admittance.....14th day
6. Development occurring within 2 weeks incubation after admittance...Within incubation period
7. Infected before or after hospitalization.....Before
8. Occurrence before or after quarantine was established.....2 weeks after
9. Contact with possible carriers.....None proved

4. *Home for Destitute Children*

1. Number of inmates.....Not given
2. Total number of poliomyelitis cases..... 3
3. Total number developed in hospital..... 3

4. Personal contact with other poliomyelitis cases .....None proved
5. Day of development after admittance..... .....5th day, 7th day, 10th day
6. Development occurring within 2 weeks incubation after admittance..... .....All cases developed within incubation period
7. Infection before or after hospitalization..... .....Contacts possible after hospitalization
8. Occurrence before or after quarantine was established ..... Before
9. Contact with possible carriers.....Possible (Children allowed to go to Prospect Park)

5. *Sheltering Arms Nursery*

1. Number of inmates..... 116
2. Total number of poliomyelitis cases..... 1
3. Total number developed in hospital..... 1
4. Personal contact with other poliomyelitis cases .....Not proved
5. Day of development after admittance....Not stated
6. Day of development occurring with 2 weeks incubation after admittance.....Not stated
7. Infected before or after hospitalization..Not stated
8. Occurrence before or after quarantine was established ..... After
9. Contact with possible carriers.....Not stated

6. *St. Joseph's Home*

1. Number of inmates.....Unknown
2. Total number of poliomyelitis cases..... 2
3. Total number developed in hospital..... 2
4. Personal contact with other poliomyelitis cases ..... Not proved
5. Day of development after admittance...Not stated
6. Development occurring within 2 weeks incubation after admittance.....Not stated
7. Infected before or after hospitalization..... .....After hospitalization
8. Occurrence before or after quarantine was established .....After
9. Contact with possible carriers.....Not proved

7. *St. Joseph's by the Sea*

1. Number of inmates..... 97
2. Total number of poliomyelitis cases..... 1
3. Total number developed in hospital..... 1
4. Personal contact with other poliomyelitis cases .....Not proved
5. Day of development after admittance....Not stated
6. Development occurring within 2 weeks incubation after admittance.....After incubation
7. Infected before or after hospitalization..... .....After hospitalization
8. Occurrence before or after quarantine was established .....Not stated
9. Contact with possible carriers...No carriers proved

Out of 21,746 children in asylums and charitable homes in the summer of 1916, fourteen cases developed, or $\frac{6}{1000}$ of 1 per cent. Of these fourteen cases of poliomyelitis there was not a single case in which direct personal contact with a patient suffering from poliomyelitis could be proved. After admission, 43 per cent of the cases developed within the incubation period of 2 weeks, and were probably infected before admission. Fifty-seven per cent. of cases developed during residence in hospital beyond incubation period, but in less than a third of these intermediate contact by carriers was indicated.

Hospitals in which cases developed after admittance.

1. *Willard Parker*, 2 cases (may have had infection before entrance). Total number of cases, 2077. Intramural development, 9/10 of 1 per cent.

2. *Kingston Avenue Hospital*, 3 cases (one doubtful). Total number of cases, 1795. Intramural development, 1.1 per cent.

3. *Kings County Hospital*, 1 case (questionable in a distant ward). Total number of cases, 103. Intramural development, 9/10 of 1 per cent.

4. *Babies Hospital*, 1 case (slight facial palsy). Total number of cases, 33. Intramural development, 3 per cent.

Hospitals admitting poliomyelitis in which there was no intramural development of the disease: Bellevue, 202 cases; Louise Minturn, 75 cases; New York City Children's, 5 cases; New York Hospital, no statement; New York Infirmary, no statement; New York Nursery and Children's, no statement; Ruptured and crippled, no statement; St. Luke's, no statement; Mt. Sinai, 58 cases; Presbyterian, 16 cases; Roosevelt, 4 cases; St. Mary's, 14 cases; St. Vincent's, 9 cases; Post-Graduate, no statement; Brooklyn Hospital, no statement; Flushing Hospital, no statement.

Orphan asylums in which no cases occurred: St. Paul's Female, number of inmates unknown; Society of the City of Brooklyn, 25 inmates; St. Dominic German Orphan House, 200 inmates; St. Malachi's Home for Children, 150 inmates; St. Joseph's Female Orphan Asylum, number of inmates unknown.

III. *Isolated Communities.*—(1) Barren Island, 350 children; (2) Governor's Island, 60 children. (No cases occurred in these communities.)

IV. *Multiple Incidence.*—The following figures are taken from Wickman's studies, and seem to throw considerable influence in favor of the contagious character of the disease:

1. Starting from school house of a community of 500, 49 cases, 10 per cent.

2. Out of 102 houses, 19 with poliomyelitis as follows: Six houses, 1 case; 3 houses, 2 cases; 5 houses, 3 cases; 3 houses, 4 cases; 2 houses, 5 cases.

3. Eighty-seven per cent. of cases in houses having more than one case.

4. Lindner and Mally's Epidemic in Steyr, 1908. Ninety-two cases in houses as follows: Thirty-four houses, 1 case; 16 houses, 2 cases; 1 house, 3 cases; 1 house, 4 cases; 2 houses, 6 cases; 1 house, 7 cases.

5. In Massachusetts epidemic, 1907, 62 per cent. of cases in houses having more than 1 case. Out of 215 families: 186 families, 1 case; 13 families, 2 cases; 1 family, 3 cases. Thirteen per cent. of cases showed multiple incidence in the same families.

6. In the New York epidemic, out of 250 families studied, the multiple incidence of more than one case in the same family was 3.4 per cent. incidence. The total multiple incidence in other epidemics, as, for example, in Buffalo, is estimated as 6/10 of 1 per cent.

7. In the study of the 7000 cases in the New York epidemic of 1916, it was found that more than one case rarely developed in the same family. There were 6521 cases, or 96.63 per cent., which did not lead to a second case in the same family. In Lynchburg, Va., cases were widely separated and distributed without relation to sanitary conditions. Three children living 14 blocks apart came down with the disease in 4 days, and Dr. Perrow of Lynchburg concluded that they could not be contact cases, but that they all got the contagion from the same source.

8. Comparative Multiple Incidence. A comparison of multiple incidence of poliomyelitis in New York City in 1916 with that of scarlet fever and diphtheria shows the following:

Cases in Same Family		Cases in Same House, but Different Family	
Poliomyelitis	335, or 56%	Poliomyelitis	257, or 43%
Scarlet fever	198, or 86%	Scarlet fever	31, or 13%
Diphtheria	73, or 78%	Diphtheria	20, or 21%

"It is evident that there is a great difference between poliomyelitis and the other two diseases in the number of later cases that have appeared in the same building, but in a different family. Thus 43 per cent. of the additional cases, or early half, appeared in the same house, but outside the family in which the original case occurred. This is more than double the number (21 per cent.) for diphtheria, and more than treble (13 per cent.) the number for scarlet fever. It seems incredible that such a divergence should exist, if poliomyelitis, like the others, were spread through infection from sick individuals, or healthy carriers, and the susceptibility of the exposed individuals is the same.

"The gradual dropping off of additional cases from day to day and the large proportion of cases occurring in other families in the house, may be easily explained on the basis of the appearance of some non-human population in the house, not definitely restricted by the boundaries which prevent intimate association, followed by its actual disappearance or inability to cause infection after a variable length of time. So far as

this evidence is concerned, this population might be composed either of insects or of higher animals such as rodents or cats."—(From a Monograph on the Epidemic of Poliomyelitis during 1916.)

In this connection, the following communication is of interest:

June 26, 1917.

Dr. Charles L. Dana,

Chairman Public Health Committee of the New York Academy of Medicine.

Dear Dr. Dana: I have read over carefully the section in Dr. Doty's report on the sources of infection, and am of the opinion that as far as the statistical basis for his deductions in favor of the contact theory goes it is unfounded. To reason that the disease is spread by contact because there were 290 cases in which 2 children in the family succumbed to the disease, 17 cases in which 3 persons were taken ill, 2 cases in which 4 persons were taken ill, and 2 cases in which 5 persons were taken ill, when in 3539 cases only one case developed in the family in which there were more than one child, is to my mind contrary to all precepts of logic. The following is a table which I have constructed on the basis of table 5 in the report by Dr. Doty:

Total number of cases of poliomyelitis investigated	4,839
Total number of families in which one child was taken ill	4,528
Total number of families with more than one child in which case of poliomyelitis occurred	3,850
Total number of families with more than one child in which only one person was taken ill	3,539
or, of the total	91.9%
Total number of families in which more than one child was taken ill	311
or, of the total	8.1%

You will notice that in this table I have eliminated all families in which there was only one child. For the remainder of the families I figured the percentage and find that in almost 92 per cent. of families with more than one child only one person was taken ill while in only 8 per cent. of families with more than one child more than one person succumbed to the disease. It seems to me that the fact that 92 per cent. of families escaped the spread of the contagion is more argument against Dr. Doty's theory than the 8 per cent. in which more than one case developed is for it.

Very truly yours,

E. H. Lewinski-Corwin,
Executive Secretary.

Dr. T. H. Weisenburg of Philadelphia made the following statement to the committee: "Personally I started out with the idea after having read Wickman's and Römer's articles and from the New York reports, that the disease was personally contagious, but the more experience I had the more I got away from that impression. To begin with in our multiple cases our data was not like your data in New York. Of thirty cases in all but two the symptoms in the second case appeared within one or at the most two days. Unless therefore, it is argued that the period of incubation is one or two days it must be admitted that there must have been a similar source of infection. Secondly, in our field study of the abortive types the evidence indicated that they appeared at the same time as the frankly paralytic cases, or within one or two days, again pointing to a similar source of infection. Third, of the cases which were admitted to the hospital but which turned out to be other than poliomyelitis, not a single one developed the disease. Fourth, there is no instance of any nurse or physician who either acquired the disease or who carried the disease elsewhere. A number of the attending physicians with young children in their families went home daily and did not carry the infection with them. I have no doubt that many more such examples occurred in New York. Fifth, because of the fact that all cases of poliomyelitis were sent to one hospital, the Municipal Hospital, we had, as was admitted in the New York report, perhaps a better opportunity to observe the disease than you had in New York. It was the impression of all the nurses and physicians that poliomyelitis was not spread by personal contact, meaning by that that it is not spread in the way that measles, scarlet fever or whooping cough is spread. If however, such a possibility is admitted, it must be that the second person must come in contact with some of the excreta such as saliva, etc. It might be interesting also to consider in this connection that in the Municipal Hospital are housed all the contagious diseases such as scarlet fever, diphtheria, etc., and that the attendants and nurses of the various units lived together, and yet there was only one instance in which a child in any other department (scarlet fever) developed poliomyelitis.

"One very striking example of the non-contagiousness of the disease was furnished us in Chester County near Philadelphia. There is in Cedar Hollow a stone quarry in which Italians work. There is a row of ten tenaments in which live about sixty Italians, forty of whom are children most of them under six years of age. The water supply was contaminated. Each family had its pigs and dogs, and the sanitary conditions were beyond belief. Two instances of the disease appeared about the same time in two families living in separate houses. There was also another case about one-half mile away in an Italian family. As is customary with these people, all of the other children and adults visited the sick children before the inspector had the opportunity to pronounce the disease poliomyelitis—indeed he did not take the trouble to quarantine them because he knew the rules could not be enforced. Here was every opportunity for the disease to spread and yet investigation by the local inspector, Dr. Mills and myself, showed that not only were there no other cases of the disease, but there were not even abortive cases."

9. Evidence of contact. Frost, at the Conference of State and Federal Health Officers, of the U. S. Health Service, said: "It is true that 75-90 per cent. of cases, on most careful investigation, cannot be traced to any previous association either direct or indirect. If it is a purely contagious disease, it must be spread from sources other than any recognizably clinically sick person, because such a large percentage must be excluded from direct contact. The spread by direct contact from schools, is not yet established, as children who have the disease are usually under school age, i. e., 1-5 years old."

V. Ineidence of Isolated Cases.—The following cases serve as examples of many similar instances: (1) Instance of a watchman, whose home was at the end of a tunnel. His child contracted the disease. Contact with diseased individual ruled out. (2) Case of cowherd, who lived 30 kilometers from next house. Three year old daughter had disease. Contact with diseased individual ruled out.

VI. Other Possibilities of Transmission.—1. Natural variations in the pathogenicity of the virus. Flexner, Clark, and Amoss found that the virus propagated in monkeys for four years, shows three phases of virulence: 1st phase. Beginning low virulence; 2nd phase. Maximum high virulence, lasting three years; 3rd phase. Low, initial virulence.

Long continued passage through monkeys causes depression in virulence while a state of latency exerts no depressing reaction. The cycle of changes in virulence seems in many ways correlated with the wave-like fluctuations of epidemics which likewise show a rise, temporary maximum and a fall in the number of cases. This conception has led to the formulation of the hypothesis of *concomitant causes* by Pettenkofer and Nägeli. Such concomitants coming rather rapidly to simultaneous maturity in extensive territories would suffice to explain the phenomena of epidemics.

2. Possibilities of animal, food, and dust carriers have not been disproved. There are three types of insects suited by their habits to serve as carriers of infectious diseases. (1) epizootic, lice and bed bugs; (2) migrant, flying insects; (3) ticks, and their allies (which, however, may be eliminated).

3. Human carriers are strongly suspected. Lucas and Osgood have demonstrated the presence of virus in nasal secretions four months after the acute stage. They were able to produce experimental poliomyelitis from washings of the nasal pharynx of parents, attendants, and friends of the patients 204 days after the acute stage.

4. Transmutations in Pathogenicity should be considered, *e. g.* (*a*) As in malaria (from mosquito to man); (*b*) As in kala-azar (from bedbug to man); (*c*) As in typhus (lice to man).

5. "Some new facts of interest and importance relating to the possible transmission of poliomyelitis by insects have resulted from the present study, but these are not so definite or complete as had been hoped. They are also to some extent of apparently conflicting nature, and require at least one unproven assumption to combine them into any working hypothesis. They do not completely disprove the idea that the stable-fly (stomoxys calcitrans) is implicated, although the behavior of the present epidemic does not favor this view. To discard it is to cast aside evidence derived from two sets of experiments, however, and it seems very unwise to do this at the present time of uncertainty. As it has been shown, it is possible with one assumption to form a working hypothesis based upon rats and fleas which seem to fit the epidemiological observations in general features and in many details as well. The general assumption that the rat can act as the reservoir for the virus of poliomyelitis should be capable of experimental proof, and it would seem that such experiments should be attempted.

"This by no means precludes the association of some other insect or warm blooded animal or both. In fact, there is a continual appearance of circumstantial evidence that suggests a population other than the human one, acting as an undercurrent and influencing the progress of the epidemic.

"When the many factors so far in doubt are gradually made known it will be possible to attack the entomological side of the question with better promise of success. Among the unknown factors which cause the greatest confusion in interpreting epidemiological evidence are: (1) the length of the period of incubation; (2) the number of mild, abortive or unrecognizable cases and carriers of the virus and their relation to infection and immunity; (3) the duration of infectivity in clincally recognized cases; and (4) positive knowledge of the presence of the infective agent in insects, domestic animals, or other possible intermediate hosts or reservoirs of the virus." (From a Monograph on The Epidemic of Poliomyelitis during 1916.)

Conclusion: All of these possibilities of communicability necessarily call the contagion theory into question. This theory leaves far too many cases unexplained. It is, therefore, not wholly satisfactory. The most compelling evidence in favor of the contagious nature of the disease, namely, the large multiple incidence, is capable of other interpretations such, for example, as focal coincidence of determinative factors. When the exceptions are so vastly in the majority they counsel against the too ready acceptance of the contagion theory. Indeed, to accept this theory in the present state of our knowledge would prove prejudicial to further advance in the matter of transmissibility.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CONNECTICUT.

March 13 *and* 14, 1917.

(*Concluded from page* 398.)

PRACTICE AND PATHOLOGY.

1. Name and give the prognosis and treatment of three of the most serious complications of scarlet fever.
2. Give the differential diagnosis between acute miliary tuberculosis and typhoid fever when tubercle bacilli are not found and Widal reaction not yet developed.
3. Describe the symptoms and physical signs of lobar pneumonia in the order of their development.
4. Give the symptoms and signs of a rather slowly developing lead poisoning.
5. Describe fully the signs in the second stage (effusion) of acute pleurisy.
6. Why do not all persons exposed to irritant pollen develop hay fever?
7. Describe the morbid anatomy of the several stages through which untreated chronic gastritis is inclined to pass.
8. Describe your treatment of a moderately severe case of lobar pneumonia in an adult having chronic nephritis.
9. How would you modify your treatment of the pneumonia in a case of arrested tuberculosis?
10. How would you treat the pneumonia in an infant of four years—giving your exact dosage and remedies?

OBSTETRICS AND GYNECOLOGY.

1. Give the clinical history, diagnosis, and management of a typical case of toxemia of pregnancy in the last few weeks.
2. Describe the normal mechanism of labor in a head presentation, occiput to the rear.
3. What are the indications for cesarean section? What are the limits of contraction in the absolute indication?
4. Give the full treatment for prolapsed cord.
5. What are the indications for the induction of premature labor? Describe a method.
6. Give the indications and contra-indications for ventral suspension or ventral fixation of the uterus.
7. Define cystocele. Give the etiology and treatment.
8. Give the diagnosis, pathology and clinical history of carcinoma of the body of the uterus.
9. Give an etiological classification of dysmenorrhea.
10. Give in full the etiology and treatment of ulcer of the cervix uteri.

SURGERY.

1 and 2. Tetanus—(*a*) Describe the germ causing it and its manner of growth. (*b*) Where are the germs chiefly found in nature? (*c*) What is the time of incubation in tetanus? (*d*) What is the prevention? (*e*) Describe the treatment.

3. (*a*) What are the causative organisms in gas producing infections? (*b*) Where are gas infections chiefly found and the reason for this? (*c*) What is the treatment?

4. (*a*) What are the symptoms of acute appendicitis? (*b*) What other conditions not infrequently simulate this disease?

5. State the advantages and disadvantages of the McBurney and the vertical semilunar incisions for appendicitis.

6. State the treatment for a recent fracture of the nose.

7. What are the symptoms of a fracture at the base of the skull?

8. (*a*) Case of thoracic empyema—Pulse for a week running 90 to 120; temperature for a week running 100 to 103; respirations for a week running 24 to 40; heart's action progressively worse; patient very weak. (*b*) Case of thoracic empyema three days' duration—Pulse 80 to 110; temperature 100 to 102; respirations 24 to 30; heart displaced, but strong and regular in action. Describe fully your surgical treatment in each case.

9. (*a*) Describe the treatment of a fracture of both bones of the forearm near the middle. (*b*) Give reasons for this rather than some other form of treatment.

10. What are the essentials in the treatment of a fractured clavicle?

ANSWERS.

PRACTICE AND PATHOLOGY.

1. *Three serious complications of scarlet fever:* (1) *Nephritis.* Prognosis is favorable under proper treatment, but the convalescence may be prolonged and the kidneys may remain susceptible to serious lesions for a long time; in grave cases uremia may occur, and lead to convulsions, coma, and death. Treatment consists of rest in bed, milk diet, hydragogue cathartics (not mercury), hot packs. (2) *Arthritis.* Prognosis is favorable, with care. Treatment consists of warm and sedative applications. The affected joints should be wrapped in cotton wool, and alkalies should be administered (salicylates tend to irritate the kidneys). (3) *Endocarditis.* Simple endocarditis has a good prognosis; the septic or toxic variety is more serious, and may prove fatal. Treatment includes the use of digitalis, strychnine, and (perhaps) alcohol.

2. In *typhoid fever* the pulse is slow and dicrotic; the fever is characteristic and generally responds to hydrotherapy; the spleen is generally (and considerably) enlarged; the rose rash is present and is characteristic; the lungs do not show any lesions; diarrhea

is quite common; intestinal hemorrhage and perspiration are common complications. In *acute miliary tuberculosis*, the pulse is more rapid and is not dicrotic; the fever has no regular cycle, but is irregular or remittent; the spleen is less frequently enlarged and such enlargement appears later and is less pronounced; there is no characteristic rose rash, but drenching sweats are common; the lungs are apt to be affected, and on examination râles, tympanitic percussion note, and pleural adhesions may be found; cyanosis and dyspnea are often present; diarrhea is not common; intestinal hemorrhage and perspiration do not occur.

3. *Lobar pneumonia. The first stage* is characterized by sudden onset with chill, a sharp pain in the side, rise of temperature, a short and sharp cough, rusty-colored, viscid sputum, and dyspnea. There may be headache, insomnia, scanty urine with diminution of urea, chlorides, phosphates, and sulphates, insomnia, and herpetic vesicles on the face, and there is always an increase in the number of leucocytes in the blood. Physical examination will reveal diminished expansion, impairment of the normal percussion note, feeble or suppressed respiratory murmur, moist or dry râles, crepitation, and sometimes a pleural friction sound.

In the second stage the dyspnea is more marked; the face is more or less livid in color; the temperature is high (104°-105° F.); and the pulse increases in rate (110-120), its tension and fullness lessening with the progress of the disease, and growing feeble and intermittent. Headache, delirium, and various other nervous symptoms may be present. Expansion is diminished and vocal fremitus is exaggerated upon the affected side. There is dullness with increased resistance over the consolidated lung, and auscultation detects bronchophony or bronchial breathing over this same area.

The third stage is ushered in by a sudden drop of temperature on or about the fifth or ninth day, followed by a natural sleep, free sweating, and relief from suffering. In this stage the subcrepitant râle (râle redux) is heard in the midst of the bronchial breathing, together with numerous moist râles. Dullness may persist for some time, but usually by the twelfth or fourteenth day the lung has returned to its normal state.—(*Pocket Cyclopedia.*)

4. "As a rule, the first symptoms presented in cases of chronic lead poisoning are debility, general malaise, attacks of indigestion, loss of appetite, constipation, thirst, and a metallic taste in the mouth. When the bowels do move, the stools are usually dark colored from the presence of lead sulphide. The urine is usually scanty and high colored. The breath is fetid. There are frequently attacks of colic in which the pain may be severe and is usually located about the umbilicus. Loss of strength, loss of flesh, cold, moist skin and a rather dull, listless expression are usually associated with it. Perhaps the most definite appearance on physical examination, and the one upon which a diagnosis may be based with a great degree of certainty, is the presence of the so-called 'blue line,' which appears along the line where the gums come into contact with the teeth. Its presence is most marked over the incisors, and is due to the deposition of lead sulphide in the capillaries of the gums. Silver and mercury may also produce a somewhat similar appearance, and it may be absent in lead poisoning, but when present to any considerable degree it is in itself almost diagnostic. In certain cases of lead poisoning the symptoms of digestive disturbances may be almost entirely wanting, while those which depend upon the effect of lead upon the nervous system may be very prominent. The most important of these are so-called 'lead-palsy' or 'lead paralysis,' which is most commonly located in the muscles of the arms, resulting in the well known 'wrist-drop.' Epileptiform convulsions occur not infrequently among the later symptoms of chronic lead poisoning."—(Dwight's *Epitome of Toxicology.*)

5. In the second stage (effusion) of acute pleurisy: *Inspection* shows bulging or fullness of the affected side, with obliteration of the intercostal spaces and displacement of the cardiac impulse.

Palpation demonstrates feeble, or absence of, vocal fremitus over the effusion, with exaggeration of the same above the fluid. The affected side is immobile, and very rarely fluctuation may be obtained. *Percussion.* Dullness or even flatness, with increased resistance may be obtained directly over the fluid, while above the effusion the percussion-note is tympanitic. The line of demarcation is higher behind than in front. Effusion of the left pleural cavity obliterates Traube's semilunar space. The fluid changes its level with different positions of the body and the area of dullness is correspondingly movable. *Auscultation.* During the stage of effusion, the vesicular murmur is feeble or absent on the affected side depending upon partial or complete compression of the lung by fluid. Above the effusion, puerile breathing is heard, and just at the upper margin of the fluid a friction sound may be heard. Vocal resonance is diminished or absent over the fluid and markedly increased above the effusion, egophony being obtained at its upper margin. With the absorption of the fluid, the vesicular murmur and the moist friction sound gradually return.—(From Hughes' *Practice of Medicine.*)

6. The persons who do not develop hay fever after being exposed to irritant pollen are probably lacking in the predisposing factors, namely an inherited tendency to the disease, chronic nasal disorder, and a nervous temperament. The people who suffer from the disease have a particular hypersusceptibility to the toxin.

7. *Chronic gastritis.* "The lesions vary considerably in different cases. In cases, mild and of short standing, the mucous membrane is thickened, pale gray color, somewhat congested, though less so than in acute gastritis, and covered by a tenacious mucus. Many dilated and enlarged veins may be visible, especially in the gastritis of portal obstruction, and there are frequently small areas of hemorrhage and pigmentation—occasionally of superficial erosion. The glands are usually choked with retained secretion and may enlarge to form small cysts. In more aggravated cases, the entire wall of the stomach participates in the process, and the mucous membrane may be thrown up into small polyp-like projections. Histologically, the lesions are those of interstitial inflammation with parenchymatous degenerations. In most cases, after the lapse of time, atrophic alterations, and more or less dilatation of the stomach, result. The mucous membrane, as well as the entire wall of the stomach, becomes much thinned, the gastric tubules atrophy and may eventually disappear and be replaced by sclerotic fibrous tissue, giving to the mucous membrane an exceedingly smooth appearance, which may be interrupted here and there by a small cyst. In rare cases the stomach becomes much diminished in size (so that its capacity may only be a few ounces), and its wall very much thickened in consequence of hyperplasia of the submucosa and muscularis."—(Kelly's *Practice of Medicine.*)

8 and 9. In both of these cases the treatment is that of pneumonia, but in the former case care must be taken lest the patient be unduly exposed to anything which may irritate the kidneys, and the diet must contain as little nitrogenous matter as possible.

The *treatment of pneumonia* "depends entirely on the type of case, and the condition of the patient. Routine treatment is the worst of all treatments. Answer the following questions before prescribing: Is the patient full-blooded, and is there a full bounding pulse? Is the pulse feeble, irregular, or intermittent? In the first case, in a young and previously healthy adult, if there be cyanosis, or signs of dilatation of the right heart, blood-letting to the extent of a few ounces may perhaps relieve the strain, but more generally treatment should be directed to maintaining the strength from the outset. In the latter case we can hope for nothing from a depressing treatment, so stimulants must be resorted to, such as alcohol, ammonium carbonate, egg and brandy mixture, quinine, ether, etc. The giving or withholding of alcohol depends upon its effect upon the pulse; should the pulse rate fall and the tongue become moist it may be continued. In asthenic cases, strychnine hypodermically is necessary from the outset, and normal saline may be given by the rectum or by the skin. Oxygen inhalations are used where there is cyanosis, but it is doubtful whether they have saved many lives. When there is evidence of failure of the heart (weakness of the second pulmonary sound, etc.) digitalis should be resorted to.

Many prescribe it from the outset. The diet should consist of milk, beef tea or broths, white of egg, and so on. The patient should be as little moved as possible, and the bed-pan must be used. As in other fevers, an airy room and good nursing are essential. Remember that narcotics are not well borne in respiratory embarrassment as a rule. Chloral should be avoided, but *if pain be excessive* a hypodermic injection of morphine does *more good* than harm, notwithstanding that theoretically morphine is contraindicated. It should not be given later than the first few days of the illness. The pain may also be relieved by poultices, which, however, are of doubtful use if carelessly made, or by application of ice. Cold packs applied to the trunk only, and frequently repeated, are very useful in relieving both pain and fever. Depressant antipyretics are to be avoided. The results of *serum treatment* are not unequivocally encouraging, but vaccine treatment would seem to be of better promise. Where possible an autogenous vaccine should be used."—(Wheeler and Jack's *Handbook of Medicine.*)

In the case with the arrested tuberculosis, care must be taken during convalescence lest the patient again show signs and symptoms of an active tuberculous process.

10. "It is a well recognized fact that *lobar pneumonia of infancy* and childhood is a self-limited disease, and that unless special indications arise no active medicinal treatment is required. This does not mean that most careful medical supervision is not desirable, or that the most intelligent nursing could well be dispensed with, or that drugs should not be administered if indicated. Without any special line of treatment the mortality of lobar pneumonia in children is less than 5 per cent. The drugs most frequently required are the stimulants. In those cases where the heart action becomes weak and rapid, the use of the ammonium preparations, such as the aromatic spirits, in 5- to 10-drop doses, may be repeated every hour or two, or the carbonate of ammonia in 1-grain doses, the taste of which should be disguised by a syrup. In extreme cases the tincture of digitalis in 1- to 3-drop doses, for a child under six years of age, or the hypodermatic injection of camphorated oil (10 per cent.) in doses of 5 to 10 drops, may be repeated at intervals of one to two hours. If cyanosis occurs, with dilatation of the right heart, strychnine used hypodermatically in doses of 1/100 to 1/150 of a grain, and repeated cautiously, seems sometimes to tide a patient over a critical period. Those cases which seem to go into a collapse during the precritical period are benefited by hypodermatic injection of strychnine or the inhalation of oxygen."—(Musser and Kelly's *Practical Treatment.*)

OBSTETRICS AND GYNECOLOGY.

1. "The important signs and symptoms of toxemia are those indicated by disturbances in digestion and assimilation, an altered state of the blood, and as a result nausea and vomiting, persisting throughout the patient's waking hours. Accompanying this is great prostration, loss of appetite, a heavy lethargic sleep, later giving place to unpleasant dreams and restlessness, the failure to retain anything upon the stomach, obstinate constipation, and substernal pain extending from the epigastrium. The pulse is rapid and grows progressively weak, respiration is sluggish, and as the disease *progresses* the matter ejected from the bowel contains an abundance of disintegrated blood cells which resemble coffee-grounds. The urine is diminished greatly in quantity, with high specific gravity, frequently albuminous, and often contains epithelial or granular casts. The nitrogen partition shows greatly lessened urea with corresponding increase in creatin and creatinin, the rest nitrogen is increased, and indican is present. Casts of various sorts are often found. As the *disease* progresses the patient in some cases becomes greatly emaciated, in others there is considerable deposit of fat, the action of the heart is progressively rapid and weak, frequently becoming thready and irregular. The mouth and gums become covered with sordes, the odor about the patient is offensive and the skin is in places the site of a purpuric or hemorrhage condition."—(Davis's *Manual of Obstetrics.*) Later on eclampsia may ensue.

The symptoms of this condition are: Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed,) very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonos, etc. The fit last fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions. For *preventive treatment:* (1) The amount of nitrogeneous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation of the uterus should, if necessary, be removed by evacuating that organ. The *curative treatment includes:* (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

2. *Mechanism of L. O. P. position.* 1. Flexion. 2. Descent. 3. Rotation, in the majority of cases all the way round to the symphysis pubis (when, on reaching left acetabulum, it, of course, becomes converted into a L. O. A. position); in the minority of cases backward rotation of occiput to sacrum. 4. Extension of occiput downward and backward over perineum, while forehead, nose, and chin, successively escape under public arch. 5. Restitution, internally of shoulders, right one to pubes, left to coccyx; externally of occiput to left thigh (thigh corresponding to the sacroiliac synchondrosis at which it originally presented).—(King's *Obstetrics.*)

3. The *absolute indications for cesarean section* are: Extreme pelvic contraction or deformity in which delivery by forceps or version or symphyseotomy is impossible, and in which craniotomy is either impossible or would be more dangerous to the mother; the presence of extreme atresia of the vagina; rupture of the uterus; sudden maternal death. A pelvis of seven centimeters or less in its conjugate diameter is an indication for cesarean section.

4. *Treatment of prolapsed funis* consists in: (1) Not rupturing the membranes prematurely unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually or with some form of repositor; (4) speedy delivery, by forceps or podalic version. If the child shows signs of asphyxiation, the various methods of artificial respiration should be tried and persisted in.

5. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head. The methods that may be employed are: Partial dilatation of the cervix and the introduction within the cervix (and vagina) of a tamponade of sterile gauze; (2) dilatation of the cervix; (3) puncturing the membranes; (4) introduction of soft rubber bougie into the uterus; (5) intrauterine injection of glycerine, water, or some other fluid.

6. *Ventrofixation* consists in fixing the uterus to the anterior abdominal wall; it is performed for displacement of the uterus, and is often more satisfactory than

shortening the round ligaments. Hermann (*Students' Handbook of Gynecology*) states objections to this operation as follows: "(1) Its risk. Oversights will occur in the practice even of the most careful; but the risk is very small. (2) Adhesions within the peritoneum are sometimes absorbed. They are absorbed often enough to make stitching of peritoneum to peritoneum unsatisfactory. After abdominal section ventral hernia may first develop after the scar has held firm for twelve years, and possibly the new attachment of the uterus may also, after many years, give way. (3) The operation lifts up the uterus. If the vulval orifice is very large there may still be a protrusion of the vaginal mucous membrane. It is well, therefore, to precede ventral fixation in women past child bearing by posterior colporrhaphy. (4) It is said to cause difficulty in labor, should the patient become pregnant. It does not always do so, and in many cases reported as illustrating such difficulty, the ventral fixation was not the cause of the difficulty. Ventral fixation after colporrhaphy, if the result be permanent, relieves the patient of any necessity for the continual readjustment of a pessary, and lifts the uterus up effectually. Ventral fixation is not advised in cases in which the womb can be comfortably kept up by a pessary."

7. *Cystocele* is a hernia of part of the bladder into the vagina, covered by the mucous membrane of the anterior vaginal wall. *Causes:* Lacerated perineum, prolapsed uterus, relaxation of the structures forming the pelvic floor, and subinvolution of the vagina after labor.

For radical cure of cystocele: "The patient is placed in dorsal position. The posterior vaginal wall is kept out of the way with a weighted speculum. The cervix is drawn down with a bullet-forceps. With a pair of tenacula the sides of the prominence are drawn together in the median line in order to see how much of the wall is redundant and these points are marked with small nicks. Next, the whole surface is put on the stretch between four pairs of forceps—one at each of the sidemarks, one near the cervix, and one at the transverse ridge at the inner end of the urethra. With a pair of scissors curved on the flat, a strip about ¼ inch wide is cut out of the mucous membrane. Similar strips are removed on both sides until an oval is denuded. Finally a running suture of chromicized catgut is passed under the whole pared surface, uniting the edges from side to side." If necessary, a perineorraphy should be done at the same time.

8. *Cancer of the body of the uterus is diagnosed* by the history, symptoms, and physical signs. It is a disease of advancing years, and generally occurs after the menopause; nulliparæ and multiparæ are equally liable. The chief symptoms are hemorrhage and discharge with an offensive odor, pain, and cachexia. The cervix is soft, the uterus enlarged and tender.

Pathology: Cancer of the body occurs *in less than 2 per cent. of all cases.* It is more frequent in *nulliparæ* than *carcinoma cervicis*, and tends to occur rather *later in life* than cancer of the cervix. The disease begins *superficially* or *deeply in the mucosa. Epithelioma, malignant, adenoma, adeno-carcinoma,* and *pure carcinoma* are found, the latter being of the *scirrhous* or *medullary type.* In the malignant adenoma there is an *atypical proliferation of the glands;* they become folded up *irregularly;* the intervening connective tissue may be *very scant,* and the gland spaces may *touch at points.* They are lined with a *single layer of columnar epithelium.* In the adeno-carcinoma, parts may show the structure of the *malignant adenoma,* and parts that of the *ordinary* cancer where the *loculi are filled with epithelial cells.* These growths form *swellings in the wall.* When near the cavity, the *mucosa may ulcerate over them.* Gradually the *uterus becomes excavated.* Adhesions *may* form with *adjacent structures,* and secondary deposits develop in the peritoneum, ovaries, tubes, vagina, etc. The epithelioma may grow *diffusely* through the *whole cavity,* or as an *isolated fungoid growth,* which may become polypoidal. Metastatic nodules may form in *different parts of the uterine wall.* These tumors are covered with *layers* of *polyhedral cells;* very rarely *pavement epithelium* is found like that in ordinary epithelioma. The mucosa of the body gets thinned."—(Webster.)

9. *Dysmenorrhea is classified* as: Congestive, ovarian, membranous, obstructive, and neuralgic. *Causes:* Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis or obstruction of the cervix, prolapse or displacement of the uterus.

10. An *erosion* of the cervix is an area on the vaginal surface of the cervix which is covered with columnar epithelium, and consequently presents a reddened, inflamed appearance. Some confusion has resulted from the application of the term *ulceration* to this condition. There is no ulcer and no granulating surface, for the whole area is still covered with epithelium. The erosion is caused by an irritant vaginal or uterine discharge (*e.g. gonorrhea,* endometritis). The causes are unknown; friction, ill-fitting pessaries, carcinoma, tuberculosis, chancre and chancroid have been said to be causative factors. *Treatment:* A possible cause should be sought for and corrected. The general health will be improved by the administration of preparations containing iron, such as Blaud's pill, Basham's mixture, and the four chlorides. Exercise, diet, and the condition of the bowels should receive attention. The local treatment consists in the administration of hot vaginal douches two or three times daily; the use of glycerine tampons for twelve hours, twice a week; the application of tincture of iodine to the cervix, once a week; and the application of silver nitrate, zinc chloride, pure carbolic acid, or Churchill's tincture of iodine directly to the cervical mucous membrane.

SURGERY.

1 and 2. Tetanus is caused by the bacillus of tetanus, which is a rodlike organism, with one end somewhat enlarged owing to the presence of a spore. It is anaerobic, and is found chiefly in punctured wounds; it can also grow on surface wounds when pyogenic cocci absorb all the oxygen. It is found in the soil. The period of incubation is about ten days. Prevention lies in the careful disinfection of all wounds; punctured wounds should be enlarged, disinfected, and drained; antitoxin is recommended by some. Treatment consists in excision of the affected part (if possible), followed by dressing with antiseptic fomentations. Tincture of iodine is a good antiseptic. Antitoxin has been used. The patient should be isolated and kept quiet in a darkened room. Bromides, chloral, morphine, and even chloroform may be required. Venesection followed by intravenous infusion of salt solution is sometimes employed.

3. The causative organisms in gas-producing infections are the *Bacillus aerogenes capsulatus, Streptococcus pyogenes, Staphylococcus pyogenes,* the bacillus of malignant edema, and the *Bacillus coli communis.* Gas infections are chiefly found in injuries which have destroyed the circulation of the part, and in which the general resistance of the tissues has been lowered; crushing injuries, in which the soil and other dirt may have been ground into the tissues, are also liable to this form of infection. The gas bacilli are found in the soil, being anaerobic. Treatment consists in prompt amputation high up above the gangrene and infection. If seen very early, free incisions with constant irrigation or immersion in a warm antiseptic fluid may be of benefit. Tonics, nourishing food, and stimulants are indicated. During the war, gas gangrene has been found to affect the muscles chiefly; treatment consists in resection of the affected muscles.

4. *Symptoms of acute appendicitis:* Sudden pain in right iliac fossa, vomiting, constipation, slight fever, tenderness at or near McBurney's point; there may be localized rigidity and swelling. The patient lies on his back with the right thigh flexed.

Symptoms simulating those of appendicitis may be found in: Gastroenteritis, intestinal obstruction, typhoid fever, gastric ulcer, duodenal ulcer, salpingitis, ovaritis, kinking of ureter, renal colic, hepatic colic, ruptured extrauterine pregnancy, peritonitis.

5. The *advantages of McBurney's operation* are that no nerves are severed and there is little or no chance of an abdominal hernia after the operation. The *disadvantages* are that it is not applicable in cases where there are many adhesions, and the incision cannot be enlarged at will.

The *vertical incision* is suitable for all cases, the in-

cision can be extended and almost any point be reached; but there is a possibility of hernia after the operation, and nerves are severed.

6. *Treatment for a recent fracture of the nose:* External pressure aided by padded forceps in the nostrils; plugging of the nostrils; a moulded gutta-percha splint fixed over the nose by a bandage; sometimes a Mason pin is required.

7. FRACTURE OF BASE OF THE SKULL. The *Signs* are those of (1) injury to the brain, (2) escape of cranial contents, (3) injury of cranial nerves. (1) *Injury to the brain* may be of the nature of concussion, compression, or laceration. (2) *Escape of cranial contents,* which may be blood, cerebrospinal fluid, or rarely brain itself. 1. *Hemorrhage* manifests itself in various situations, according to the position of the fracture. In the *anterior fossa* the bleeding may be from the nose or into the orbit, or may pass back into the pharynx, be swallowed, and subsequently vomited. The eye may be pushed forward and pulsate if the cavernous sinus be ruptured. In the *middle fossa* blood usually runs from the ears; but slight bleeding from the ear may be caused by minor injuries, such as rupture of the membrana tympani, tearing of the lining of the auditory canal, and fracture of the tympanic bone. In the *posterior fossa* a hematoma may form behind the mastoid process. 2. The escape of *cerebrospinal fluid* is a certain sign that a fracture communicates with the subdural space. It may appear in the same situations as hemorrhage, but is usually found escaping from the ear owing to fracture of the petrous bone. The fluid is limpid, specific gravity 1005, with no albumin, but containing pyrocatechin, which gives the same reaction as sugar with Fehling's solution. The amount which escapes may be small or very large, but as a rule it soon ceases. (3) *Injuries to the cranial nerves* vary according to the site of fracture. That most commonly involved is the facial in the aqueductus Fallopii, and the paralysis may come on immediately from rupture, or after two or three weeks from the pressure of callus. —(From *Aids to Surgery.*)

8. "Although it is true that aspiration will occasionally cure a pneumococcal empyema in a child, it is generally regarded by surgeons as an exploratory or palliative measure. For the latter purpose it may be used in cases of rapid phthisis, or as a preliminary measure to operation in bad cases in which the effusion is very large or exists on both sides. With these exceptions, *thoracotomy* (opening the pleural cavity), with or without resection of a rib, is recommended in all cases. *Thoracotomy without resection* of a rib is indicated when the patient's condition is very serious, as it is easily performed under local anesthesia, by making an incision about two inches in length along the lower border of the sixth or seventh intercostal space in the midaxillary line. A small opening is made in the pleura, in order to allow the pus to escape slowly; the opening is then enlarged, loose pieces of lymph removed, and a short rubber tube introduced. The tube should be sutured to the skin, to prevent its expulsion, and transfixed with a large safety pin, to prevent its dropping into the cavity. *Resection* of a portion of a rib is the usual operation, as it allows more room for exploration and free drainage. Ether is contraindicated, because of its effect on the lung. The best general anesthetic is nitrous oxide and oxygen, but chloroform or a local anesthetic may be employed. The patient lies on his back and is brought to the edge of the table. A two or three inch incision, with its center in the midaxillary line, is made over the seventh rib, and the periosteum divided, and separated from the entire circumference of the rib with closed curved scissors or a periosteal elevator. The rib is divided at each extremity of the incision with bone forceps and removed, the intercostal vessels having been pushed aside with the periosteum; the operation then proceeds as in thoracotomy without resection of the rib. Irrigation of the cavity should never be employed in acute cases, as it is occasionally followed by death. In chronic cases, however, in which the adhesions are firm, irrigation with sterile salt solution is often advisable, particularly if the discharge is very fetid. The tube may remain in place until the purulent discharge ceases, or, better, it may be removed at the end of a week, and a Bier suction pump used once or twice daily until the lung is fully expanded. If the sinus persists (pleural fistula), there is caries of a rib or non-obliteration of the cavity. In either case a secondary operation will be required. If the lung fails to reach the chest wall after several months, the chest wall should be taken to the lung by *thoracoplasty* (Estlander or Schede operation). One may first try, however, injection of Beck's bismuth paste. The cavity is filled with mixture No. 1 (not more than 100 grams being used) and the opening allowed to close. If the temperature rises above 101° or severe pressure symptoms appear, the accumulated fluid is evacuated and the opening again allowed to close. Repetition of the injection is necessary only when the paste is discharged with the pus. *Estlander's operation* consists of the resection of a sufficient number of ribs, with the periosteum, to obliterate the abscess cavity. The length and number of ribs to be removed depend upon the size of the cavity. In a large cavity it may be necessary to remove three or four inches of all the ribs from the third to the ninth. This is best done through an I or U-shaped incision, although separate incisions may be made in every other intercostal space, and the rib above and below removed through each incision. The cavity is emptied of all debris and packed with gauze. *Schede's operation* is more radical and more severe. A U-shaped incision is made from the origin of the pectoralis major at the level of the axilla, down to the lower level of the pleural cavity, then up to the level of the second rib between the spine and the scapula. This flap is reflected upward, and all the ribs over the cavity from the second down, and from their tubercles to the costal cartilages, excised together with the periosteum, intercostal structures, and thickened parietal pleura. Bleeding is checked, the cavity curetted with gauze, and the flap sutured so as to lie in contact with the long, drainage being provided by sterile gauze. After any operation for empyema pulmonary gymnastics should be given to expand the lung. The patient should also have been informed that the resulting deformity is necessary to the cure."—(Stewart's *Surgery.*)

9. In fractures below the insertion of the pronator teres the forearm is placed midway between pronation and supination, and the interosseous space preserved by means of pads. In fractures above this point the forearm should be put on an anterior angular splint, in full supination. If there is a persistent tendency to ulnar bowing of the forearm, *i.e.* convex toward the ulnar side, the elbow may be extended and a long straight splint or a plaster cast applied.

The essential point is to prevent the growing together of the four fragments in one bony mass, with consequent loss of pronation and supination. Hence, the radius and ulna are kept as far apart as possible, namely in a position halfway between pronation and supination.

10. *The essentials in the treatment of a fractured clavicle,* are to correct the deformity as soon as possible, by fixing the shoulder upward, outward, and backward. The patient may be placed on his back, on a hard bed, with a small pillow under his head and a firm and narrow cushion between the shoulders, a bag of shot on the site of the fracture, and the forearm lying on the front of the chest, while the arm is kept close to the side by a sandbag.

Arsenic Content of Normal Urine. — Ivar Bang has shown that arsenic to the extent of a definite percentage may be present in normal urine. Of twenty-seven subjects studied only three had no arsenic in their urine. Fifteen others showed up to 0.1 mgm. in the diurnal urine and in nine others the amount ranged from 0.1 to 0.2 mgm.—*Hospitalstidende.*

Eclampsia Not Prevented by Certain War Conditions. —It having been asserted that absence of eclampsia was due to low diet or to absence of coitus during pregnancy Lichtenstein announces that there has been no percentage decrease of eclampsia in Germany as a whole, or at least that such cannot be shown. In individual clinics some decrease in incidence can be accounted for by various factors. In Leipzig a decrease began before the war; the birth rate has fallen off; cases from outside the city are fewer, etc. If eclampsia is less common so too is placenta previa, and for just the same reasons.—*Zentralblatt für Gynäkologie.*

DIABETES INSIPIDUS IN CHILDREN.*

BY RUDOLPH DURYEA MOFFETT, M.D.,
NEW YORK.
ASSISTANT VISITING PHYSICIAN TO THE A. JACOBI DIVISION FOR CHILDREN, GERMAN HOSPITAL,
AND
MORRIS GREENBERGER, M.D.,
NEW YORK.
HOUSE PHYSICIAN, GERMAN HOSPITAL.

THE literature concerning diabetes insipidus in general is quite extensive, despite the relative rarity of the condition. That which deals especially with the affection in children, however, is limited, both in scope and volume. In many of the textbooks on pediatrics the subject is disposed of with a few lines, or at most a few pages; and the major number of references encountered are found to be merely reports of cases.

A compilation and analysis of all the cases reported to date would prove more tedious and difficult than the value of such an undertaking would warrant, because of the fact that so many cases in children are reported in general discussions of the subject of diabetes insipidus, with nothing in the title to suggest that children are concerned. Furthermore, many cases are now dealt with under the various phases of endocrinology, and to differentiate those in which the diabetes insipidus forms merely a part of the entire ductless glandular syndrome from those in which the polyuria, polydipsia, and other symptoms of diabetes insipidus give chief color to the pathological picture, would be a task fraught with many difficulties.

The fact that so little specific attention has been devoted to the discussion of diabetes insipidus in children is the more remarkable when one recalls the percentage of cases occurring before puberty. According to von Noorden[1] 10 to 15 per cent. of the total number affected occurs in the first decade, the majority of these being in the second half of this decade. Garrod[2] states that about half of all cases are in patients between the ages of ten and forty years. The figures of Gerhardt,[3] so often quoted, give sixty cases, compiled from the records of four observers, occurring in patients under ten years of age. Of these, thirty were in children between five and ten, and thirty under five years of age.

The occurrence of diabetes insipidus in early infancy is indeed rare, as the above figures would indicate. Rachel[4] was not able "to find the record of a case while scanning the literature pretty carefully." He reported four cases, however, of his own, four, five, ten, and eleven months of age respectively. Among the cases in children encountered in the literature, only one other, reported by Brunton,[5] was an infant under one year of age.

In children, as in adults, the larger proportion of cases occurs in males. Of thirty-six individual cases encountered in the published reports reviewed, twenty-eight were in males and eight in females. Since these reports range in date from 1888 to 1916, it is fair to assume that this proportion holds.

CASE.—B. S. was admitted to the Children's Service of the German Hospital on Jan. 14, 1917, born in the United States, age 6 years. Male child. Chief complaint was of frequent urination and pain on urination.

Present History.—For 2 months patient has had frequency of urination. He has both diurnal and nocturnal diuresis, urinating about every hour. Micturition is accompanied by pain and burning occasionally. Patient has moderately severe pains in the hypogastric region. He has also been troubled with urgency and slight urinary tenesmus, but no blood was ever noted in the urine. He is always very thirsty and feels hot at times. At other periods has sensations of chilliness; feels weak, and has lost weight. His appetite is poor, bowels are fairly regular. Has a very slight cough.

Past History.—He had measles at two years. Tonsillectomy was performed last year. He had no history of sore throats and no other illnesses. There was no history of trauma to the head.

Family History.—Father and mother are both alive and well. There are three other children in the family, alive and well. There is no history of any member on either side having had a similar condition.

Physical Examination.—A poorly developed and nourished male child, who appears apathetic and somewhat prostrated. Has no other evidence of acute disease.

Head: Scalp clean. Hair light. Pupils are equal and react to light and accommodation. No strabismus. Lips are dry and crusted. Teeth are decayed, and a few missing. The tongue is heavily coated. No tonsils present. Pharynx slightly injected. Few small glands felt in the neck. No rigidity of the neck.

Chest is very thin and poorly developed; expansion fair. Heart apex is visible as a diffuse impulse and is felt in the fifth intercostial space at the nipple line. No thrill is felt. The sounds at the apex are loud, the first sound being accompanied by a slight systolic murmur. The second pulmonic is accentuated, reduplicated and loud. Brachial arteries are seen to pulsate. A pistol shot sound is heard at the femorals. The pulse is regular, of fair quality, but somewhat thin. Moderately rapid; not of the Corrigan type.

At the upper lobe of the right lung along the spine some dullness and increased expiratory phase are noted. An occasional rale is heard in the chest.

The abdomen is soft and flat, no rigidity, no masses felt. Some tenderness obtained in the hypogastric region. Extremities present no edema or eruption, no clubbing; they are both cold and moist. Reflexes are markedly exaggerated, no clonus or Babinski. Small glands are to be felt in the axillæ, cervical and inguinal regions. No abnormalities of the genitals noted.

Examination of blood: Hemoglobin, 90 per cent.; white blood cells, 10,500; polymorphonuclears, 53 per cent.; small lymphocytes, 47 per cent. Culture of

*From the A. Jacobi Division of the German Hospital.

throat for diphtheria, negative. Von Pirquet reaction positive. Blood pressure, 105 systolic. Schick test negative. Blood, Wassermann, negative. Spinal fluid globulin negative, cell count, normal. Wassermann on spinal fluid, negative.

Examination of urine:

Reaction.	Specific Gravity.	Color.	Albumin.	Sugar.	Microscopical.
Acid	1005	Watery	0	0	Few white blood cells
Acid	1001	Watery	0	0	Negative.
Acid	1002	Watery	0	0	Negative.

Chemical examination of blood: Urea N 10 milligrams per 100 cc.

Creatinine 1:0.

Sugar as dextrose 0.066 per cent.

Special chemical examination of urine:

Chlorides as NACl 1.6 gms. in 24 hours.

Total Nitrogen 22.6 gms. in 24 hours.

cardiac shadow: Lateral 10 cm., M. R. 2.5 cm., M. L. 7.5 cm."

On February 21 another *x*-ray examination was made by Dr. W. H. Stewart, who reported: "On Jan. 19, I examined this child's head to ascertain if there were any Roentgenographic signs of pituitary disease. At that time I reported negative although we found a shadow behind the posterior clinoidal which seemed abnormal. We were unable to explain what this indicated. Upon re-examination on Feb. 20 we found that the above shadow is distinctly increased and I am now suspicious that it represents some tumor mass in this region, probably involving the hypothalamus, but not disturbing the sella turcica."

January 22. General condition apparently good. Drinks enormous amounts of water and passes large amounts of urine. Complains of pain in abdomen if water is not supplied. No abnormalities in the abdomen made out. Kidneys are not palpable or tender.

January 29. The patient has been on a salt free diet for several days. Very little change was noted in the intake or output of fluids.

January 31. Ice pills were tried for several days

Ammonia 1:40 grms. Ammonia N. 1-13 grms. 5 per cent.

Urea 36.4 grms. Urea N 17.0 grms. 77 per cent.

Examination of urine for inosite—negative.

Examination by Dr. E. Henes, Jr., of blood for cholesterol—normal.

January 23. Sugar tolerance test done. 100 grams of glucose given and no sugar obtained in urine, specimens being collected every hour for 8 consecutive hours and for the entire 24 hours.

February 23. Eyes examined by Dr. Denig. He found a beginning atrophy of the left temporal disc. The right was normal.

The following day the patient was examined by Dr. G. W. Jacoby. The above findings were verified. The possibility of cranial abnormality was considered. The skull was noted to be broad and flat.

x-ray examination of the thorax was made by Dr. Wm. H. Stewart on January 23, who reported: "We do not find sufficient Roentgenographic evidence to justify us in making a diagnosis of tuberculosis nor is there any marked cardiac enlargement. The following approximate measurements will give an idea of the

but the thirst was apparently not diminished.

February 3. Injections of atropine sulphate have been used with very little result.

February 7. Pituitrin has been used several days with very good result. The thirst is markedly diminished. The general condition is very good.

NOTE.—During the patient's stay in the hospital the amount of fluid intake varied from 1,000 c.c. per day to 9,000 c.c. per day, depending upon what treatment the child was receiving, which can be observed by an examination of the chart. The same was true of the fluid output in the urine, which varied from 7,000 c.c. to 2,000 c.c. per day. This great difference in the amount of fluid output and intake was markedly influenced by the use of pituitary extract given in ½ c.c. doses hypodermically twice a day. The reader should refer to the chart. A discussion of the history will be taken up more fully under the conclusion.

The study of the above case led us to make a fairly comprehensive review of the entire subject of diabetes insipidus, as given in the published reports of various observers. We have made an especial effort to study carefully all of the cases which have occurred in children. Short abstracts have been inserted in the text in order to show the observations and investigations which have been made by other workers and additional references are given in the bibliography.

Historical.—Thomas Willis,[6] of "Circle of Willis" fame, in 1674, first directed attention to the fact that the urine of diabetic patients is sweet to the taste; in other words, that in some cases of polyuria the urine is sweet and in others not so. This led to the classification of saccharine and non-saccharine diabetes.

Simmons,[7] in 1792, reported two cases of polydipsia, one of which was said to be a "drought without example." According to Fitz,[8] these are the first cases of diabetes insipidus recorded in English, though not so called.

In 1794, two years after the publication of Simmons' cases of "drought," Frank[9] first defined the condition, in accordance with Willis' discovery, as a long-continued secretion of urine, non-saccharine in character. He called this diabetes insipidus, or spurious diabetes, as differentiated from diabetes mellitus, or true diabetes.

The first attempt at a classification of the cases of diabetes insipidus was made by Robert Willis,[10] in 1838. This classification, which no longer holds, was based on the amount of solids contained in the urine.

The experimental study of diabetes insipidus was inaugurated in 1849, with the well-known animal experiments conducted by Claude Bernard,[11] who found that injury to a certain point in the floor of the fourth verticle, just above the so-called "diabetic center," produced transitory simple polyuria. In addition to his observations upon the central nervous system, Bernard conducted stimulation, section, and other experiments upon various individual nerves.

Eckhard[12] produced temporary polyuria by injury (mechanical), and irritation (chemical and electrical) of the vermiform process of the middle lobe, and injury of the posterior lobe, of the brain.

Kahler[13] was able to produce permanent polyuria, accompanied by polydipsia, in rabbits, the condition resembling diabetes insipidus in man. He accomplished this by injecting minute quantities of concentrated silver nitrate solution into various parts of the brain.

Ralfe,[14] in 1897, pointed out the possible effects of remote lesions of the nervous system on urinary secretion.

The discovery by Schäfer and Magnus[15] of the diuretic effect of extract of the posterior lobe of the pituitary gland, and the observation, by Schäfer and Herring,[16] that the renal arteries are exempt from the constricting effect exercised by this extract upon other vascular channels and upon unstriped muscle in general, were important links in the chain of evidence leading to the association of diabetes insipidus with the hypophysis cerebri.

Frank[17] believed that many cases of diabetes insipidus result from hypersecretion of the pituitary gland, with resultant diuretic effect, holding to the view that this secretion does not exercise the constricting action upon the renal vessels that would be inferred from the rise of blood pressure. This latter view, it will be noted, is in keeping with the observations of Schäfer and his coworkers.

It is impossible, in this review of the subject, to do more than cite some of the more distinctive links in the chain of evidence whch has brought clearly to light an etiological relationship between the hypophysis and at least a certain proportion of (some maintain all) cases of diabetes insipidus. It may be said, however, that the brilliant work of Cushing[18] and his associates, together with the many observations upon the subject from the point of view of the endocrinologist, have served to focus both experimental and clinical attention in this direction.

Despite this trend of opinion toward the cerebral or endocrine origin of diabetes insipidus, certain observers, notably Tallqvist,[19] Meyer,[20] Seiler,[21] Socin,[21] and Rosenbloom and Price[35] have maintained that diabetes insipidus is the result of a primary inability on the part of the kidneys to excrete urine of normal concentration. Schwenkenbecher,[22] Falta,[60] Finkelnberg,[23] and Forschbach and Weber,[24] among others, have expressed the view that the excretion of large amounts of urine is the result of some pathological condition giving rise to stimulation of the kidneys, rather than the outcome of primary incapacity for concentration on the part of these organs.

Etiological Factors.—From a study of the reported cases, whether adults or children, it would seem that certain predisposing factors play a part in the production of diabetes insipidus. The influence of age and sex, as apparent in the histories of reported cases, has already been noted. Heredity has long been thought to bear an etiologic relationship to this affection, and the remarkable collection of cases of familial diabetes insipidus published by Bulloch[25] seems to bear out this view. It is held by many that an hereditary influence is not incompatible with organic inefficiency of the kidney with endocrine disturbance, or with any of the other factors which have been proposed in the effort to discover the etiology of diabetes insipidus.

The clinical classification of cases as *primary* or *idiopathic*, and *secondary* or *symptomatic*, which was so long accepted as being satisfactory, has been challenged in the light of modern research. It has given way to another, based upon the three leading theories of etiology, viz., (1) that the condition is due to faulty concentrative powers on the part of the kidneys; (2) that it is a primary polydipsia, the renal function being normal; (3) that it is the result of a stimulation of the kidney from different causes, the polyuria being symptomatic. Added to these, or included with them, is the view that the condition is the result of hypersecretion of the hypophysis. As previously stated, attention is now chiefly centered upon disturbance of function of the hypophysis from whatever cause arising, as the prime factor in the production of diabetes insipidus.

The disturbance of function of the hypophysis is generally considered as being hypersecretion. To this view, however, there are dissenting opinions. Meyenburg[26] expressed the view, based upon his

clinical and experimental observations, that the endocrine disturbance is one of hypo- and not of hypersecretion. Simmonds,[27] studying secondary growths of the pituitary body in connection with diabetes insipidus, concluded that this affection, if of pituitary orgin, is due not to a hyperfunction but to an absence of function of this organ. In one of his cases, a boy, nine years of age, who had not developed well since his fifth year, there was polyuria, intense polydipsia, and extreme emaciation. Postmortem examination revealed a hemorrhagic tumor of the size of a walnut on the floor of the third ventricle, projecting toward the sella turcica. The pituitary body was macroscopically normal; microscopically, however, the posterior lobe and the stalk were invaded by sarcomatous tissue of the same structure as that of the tumor of the third ventricle.

From certain clinical observations, coupled with assembled experimental data, Cushing[15] suggested that not only are the emotional polyurias, in all probability, the expression of a neurogenic discharge of hypophyseal secretion, but that the clinical polyurias are, in many instances, merely symptomatic expressions of an internal secretory disturbance brought about by injury or disease involving the hypophyseal region. "Hence," he said, "whether or not there actually proves to be a form of polyuria of primary renal origin, our present conceptions of so-called diabetes insipidus need to be recast, with especial reference to the factor of the secretory activity of the pituitary body and particularly of its posterior lobe."

Summing up the question in 1914, Brown[28] said: "The conclusion that we are forced to is that there is no such thing as idiopathic diabetes insipidus. The hypophysis cerebri may be irritated by syphilitic meningitis, tumors, injury, or other nervous stimuli, and throwing more of the secretion of its posterior lobe into the circulation causes polyuria. Some of the cases in which the permeability of the kidney is damaged are simply cases of chronic interstitial nephritis. In others this condition is also associated with hypophyseal disease, which may perhaps have set up a secondary injury to the kidney by raised blood-pressure. For although interstitial nephritis may induce a rise of blood-pressure it is also true that interstitial changes in the kidney may be induced by vascular disease as is seen in the arteriosclerotic kidney. A polyuria secondary to polydipsia is not diabetes insipidus. At the present time the hypophysis seems to be the dominating factor in producing the condition to which that name may be fairly applied."

The fact that polyuria and polydipsia so frequently make their appearance, especially in children, following an acute infectious disease, led the earlier observers to conclude that the infection exercised an irritative influence upon the kidneys which resulted in polyuria of greater or less severity and permanency. In the light of endocrinological investigations, however, the hypophysis would seem to be the organ primarily affected by the toxins of the infectious disease.

In connection with the pathogenesis of this interesting condition, the following editorial summary[6] seems well worth reviewing at this point: "At one time the view was advanced that the polyuria is secondary to a chronic polydipsia, and cases have been reported in which this condition seems to have existed, but these cases are of an atypical, transient form, dependent on neuroses, and quite distinct from the typical persistent form of the disease. Strubell found that in the typical cases a rise in the concentration of the blood soon follows a brief period of thirst, showing that the excessive renal secretion is not dependent on an excessive amount of liquid in the blood, as is the case in polyuria resulting from polydipsia. This and other observations have led to the view now prevailing that diabetes insipidus depends on a functional abnormality in the kidneys, which is not the sequel of any evident structural alteration, but rather depends on some change in either the vascular or nervous mechanism of the kidney. In many instances there is definite evidence of nervous involvment, as in two cases studied by Seiler in which the disease followed fracture of the base of the skull, and it may be recalled that Claude Bernard, in his classical experiments on experimental glycosuria, found that lesions of the medulla might be followed by polyuria without glycosuria. There are many cases, however, in which no central nervous lesions can be demonstrated, and some in which hereditary influences bear a part.

"According to many observers, the increased flow of urine depends ultimately on a dilatation of the renal vessels, unaccompanied by general rise in arterial pressure; presumably this vaso-dilatation is the result of the primary nervous lesions, for a similar condition of polyuria is said to be produced in animals by cutting the renal nerves. R. Schmidt believes it possible to modify the course of the disease by reducing this renal hyperemia through artificial hyperemia of other vascular regions; *e.g.* catharsis in cases with obstipation, and external heat or diaphoretics in patients with dry skins. Spaether also considers diabetes insipidus to be the result of a paresis of the renal vasomotor nerves, of either central or peripheral origin; and he explains the favorable results which sometimes follow the method of treatment by strychnin injections advocated by Feilchenfeld, as due to stimulation of this nerve plexus.

"Studies of the conditions of metabolism in this disease seem to prove that it is not the cause or the result of metabolic disturbances, but apparently depends exclusively on secretory abnormalities. Tallqvist made the interesting observation that variations in the amount of nitrogenous food cause a corresponding variation in the amount of urinary secretion, so that the proportion of urea in the urine remains practically constant; the same change followed variations in the amount of sodium chloride in the food. A. Wolf found that the reverse is also true, namely, a reduction in the quantity of the urinary secretion by any means leads to an equal reduction in the amount of urea excreted, the proportion remaining constant. These results are confirmed in a careful study from Sahli's clinic by F. Seiler, who found that ingestion of large quantities of nitrogenous food is not followed by a rise in the specific gravity of the urine, as is the case with normal individuals. Apparently in diabetes insipidus the kidneys can not excrete urine containing nearly so large a proportion of solids as normal urine; therefore, the total excretion of solids

can reach the normal only when a sufficiently large quantity of water reaches the kidneys to carry out all the accumulating solids of the blood. Should there not be sufficient water to accomplish this, the concentration of solids in the blood will increase, leading to the sensation of thirst which causes the characteristic polydipsia and polyuria of the disease. Seiler suggests that the polyuria of chronic interstitial nephritis similarly may depend on the sensation of thirst produced by an increase in the concentration of the blood due to retained solids. In diabetes insipidus, however, uremia does not follow, because there are no renal lesions to prevent the polyuria being sufficient to remove all excess urinary solids from the blood. Just why the kidney is unable to secrete a normally concentrated urine in diabetes insipidus Seiler does not attempt to explain, beyond ascribing it to nervous defects. He does not believe the view held by Tallqvist, that there is a failure of resorption of water from the tubules, can be the correct explanation."

Symptomatology and Diagnosis.—The symptomatology, as stated by Futcher,[29] is as follows: Polyuria; polydipsia; absence of sweating; appetite poor; constipation the rule; ocular changes (cataract, xanthoma palpebrum, pigmentary choroiditis, incipient or advanced optic atrophy, etc.); headache; lumbar pains; impotence; blood-changes—slight; loss of weight; edema of feet; knee-jerks exaggerated; metabolism not much disturbed.

The presence of polyuria and polydipsia suggests the diagnosis of diabetes insipidus. The study of the urine gives the most conclusive evidence. According to Koplik,[30] if the daily amount of urine is three or more times the normal amount, there is polyuria. The specific gravity does not exceed 1.006. The urine is light-colored.

The polydipsia, which may first direct attention to the condition, is generally extreme, and not the least distressing symptom. Instances have been recorded in which the thirst was so great that the individual, whether adult or child, would go to the extreme of drinking water from puddles of water, from waste vessels, some even drinking their own urine, in order to quench the veritable "drought" which consumed them.

The other symptoms vary greatly. In some of the cases reported the polyuria and polydipsia were the only symptoms of consequence, the patient being otherwise fairly comfortable and healthy.

Prognosis.—The prognosis of diabetes insipidus depends largely upon other conditions and upon the causative factors. Cases have been reported by Brunton,[5] Guthrie and Sutherland,[31] and others, in which the condition proved to be transitory, leaving little or no ill after-effects. Those who hold the view that diabetes insipidus, like diabetes mellitus, sometimes comes under the category of an "emotional" disorder, give a favorable prognosis in such cases. Polyuria and polydipsia may continue through life, as von Noorden[1] has pointed out, "as an inconvenience rather than a disease." As a rule, however, in true diabetes insipidus the prognosis is considered unfavorable. To what extent the prognosis will be modified in future by treatment along the lines suggested by the endocrine origin of the affection cannot at present be predicted.

Treatment.—The treatment of diabetes insipidus, as given in the literature, varies with the symptomatology, and with the individual conception of the etiology of the affection, from dietary and hygienic measures, through the gamut of nerve stimulants, vasoconstrictors; vasodilators, and organotherapeutic agents to sella decompression and such other surgical measures as may be suggested by the exigencies of the case.

Quoting again from the editorial summary:[46] "As to therapeutics, Seiler believes that the practice of restricting the amount of fluid taken by the patient should not be carried too far, as retention of solids will result with all its evil effects. The mere reduction in quantity of urine is not a desirable result when there is not a corresponding increase in specific gravity, for otherwise retention of solids must be taking place. In some mild cases, in which the primary nervous disorder is either transitory or purely functional, reduction in the amount of fluid ingested, together with such nervous stimulants as strychnin, or vasoconstrictors, such as ergot, may lead to improvement or recovery; but it is imperative that the amount of urinary solids must remain normal as the polyuria decreases. Attempts made by Seiler to improve the function of the kidney by diuretics did not give favorable results."

Herrick, J. B.[47] has made an interesting observation in the case of an adult male which he reports because of the remarkable effect of lumbar puncture in diminishing the amount of urine and raising its specific gravity. Typical case of diabetes insipidus. Lumbar puncture was made and less than 5 c.c. of fluid withdrawn, slowly, under low pressure. Within 48 hours the daily amount of urine (7,500-11,000 c.c.) had dropped to 660 c.c.

In our treatment of this interesting condition, we began, as will be seen on the chart, by having the patient placed on a soft, non-restricted diet, with plenty of water during the first eight days in the hospital with the thought in mind of seeing just how much the water intake and the water output would be in 24 hours, and also with the idea of seeing just what had been the condition of the child during the weeks before.

Having reviewed Meyer's[26] article on the effect of a salt free diet, in cases of diabetes insipidus, we were anxious to see if this worked out in our case. This salt free diet we continued for six days with only a slight decrease in the water intake, the water output remaining about the same. For the next two days the child was given no water, was fed only a few ice pills, and this, while it lessened the water intake and output, made the child complain bitterly of abdominal pain and weakness.

Being familiar with the effect of pituitrin on the amount of water output, in some of the cases of diabetes recorded, Falta[50] and others, in the literature, we began by the injection of one-half c.c. of pituitary extract twice a day. This lowered the water intake and water output, as will be seen by the chart, to a very marked degree, and without producing any disagreeable symptoms to our patient. This we continued for eight days, keeping the urine output below 2,000 c.c. with a great dimunition in the amount of thirst, and weakness. This observation has been made by a number of other investigators, which seems to indicate that there is some

connection between the pituitary gland and diabetes insipidus.

Summary.—Diabetes insipidus is a disease which is characterized by polyuria; polydipsia; absence of sweating; anorexia, appetite poor; constipation the rule, ocular changes (cataract, xanthoma palpebrum, pigmentary choroiditis, incipient or advanced optic atrophy, etc.); headache; lumbar pains; impotence; blood-changes—slight; loss of weight; edema of feet; knee-jerks exaggerated; metabolism not much disturbed.

A study of the cause of the polyuria, from a careful investigation of a large number of histories of this condition and from the careful observations which we made in studying our reported case, leads us to believe that the whole chain of symptoms, which is so characteristic and which is always present in the true cases, has its fundamental origin in the pituitary gland and not in other parts of the body.

We must disagree with Eric Meyer and his coworkers, for we do not believe that the changes in the concentration of the urine are due to a primary disorder of metabolism, but that the changes in metabolism of the body are secondary to the disease which is present in the pituitary body.

This change in function which takes place reacts undoubtedly upon other glands of internal secretion, and upon the entire organism.

There is a good deal of evidence which leads us to believe that the changes which have been observed by Tallqvist,[19] Meyer,[20] Socin,[21] and others, in the kidney vessels themselves are only part of the result of absence of pituitary secretion.

TABLE OF CASES ENCOUNTERED IN THE LITERATURE
(Not supposed to be a complete list)

Cases.	Sex.	Age. Yrs.	Age. Mos.	Reported.	Author.
1	F	4½		1888	Weiszharth.
2	M		5	1890	Rachel.
3	F		10	1890	Rachel.

34	M	9		1914	Simmonds.
35	M	5		1915	Reuben.
36	M	4		1916	Rosenbloom and Price.

During the course of our exceptional opportunity to study the case here reported, we were able to try the effect of reduction in the amount of sodium chloride intake and of water intake over a considerable period of time, which can be seen by an examination of the chart in the text. These various experimental observations did not prove helpful at all, for the case continued passing the same large quantities of urine notwithstanding the reduction in the amount of sodium chloride intake. This observation has been made by other workers in the same field and the unsatisfactory results obtained lead us to the investigation of the pituitary body as a possible cause of the entire condition. Our observations showed that injections of a half cubic centimeter of pituitary extract two or three times a day lessened the amount of urine output to a very marked degree, there being a drop of from 7,000 or 8,000 c.c. to 1,500 to 2,500 per day. This same observation has been made by Schäfer and Magnus,[15] Frank,[17] Simmonds,[27] Cushing,[18] and others.

PROGRESS IN SURGICAL THERAPEUSIS.*

By ALBERT VANDERVEER, M.D.,
ALBANY, N. Y.

The title of my paper gives great latitude regarding the extent to which the subject may be approached. Taking advantage of this, I shall refer to but a few of the points upon which I can speak from personal observation and experience.

There is much in the surgical therapeutics of to-day that seems thoroughly reliable for us and beneficial to our patients, and yet it is too true that comparisons can be made relating to certain forms of sepsis, in which results are not much better than four decades ago. Laboratory research has done much to aid us in our precision of diagnosis, but on the other hand have we made that progress in treatment consistent with these advances? If we are candid with ourselves, must we not admit that there are too many deaths from septicemia, not only among members of our own profession, but among patients from all the various walks in life; not in one city or section, but from our country at large? To express my convictions that in our studies regarding laboratory experiments and results I am convinced that we have placed too much confidence in the mildness of certain forms of pathogenetic microbes, and forgotten somewhat our long-established knowledge of the histology and location of certain anatomical structures. We must harmonize our knowledge and become more alert in the application of wisdom.

A man at my time of life may be presuming in asserting that there are many divisions of bacteria, and various microscopical organisms that are not fully understood in their seriousness, when aroused into action, especially in structures possessing little resistance, and in alarming proximity to important organs. We are only beginning to understand that there is a variety of staphylococcus aureus much more virulent than we had ever supposed, and this observation applies to other more precise classification and new discoveries. We also understand that there are in one organ latent pathological organisms that may be started into activity by an operation, and, having an affinity for some important organ elsewhere, do serious damage. Witness what we are only beginning to recognize, and not fully understand, of myocarditis and acute dilatation of the heart in connection with our gall-bladder work.

Case I.—Mr. W. L., æt. 47, a man of excellent habits, very active in business. For nearly two years he suffered more or less from acne vulgaris, located, more especially, over upper part of back and in region of neck, assuming a condition of true furunculosis. Cultures developed the staphylococcus aureus, and under the use of autogenous vaccines he improved decidedly for a period of six months or more; then a return of the trouble presented itself. He was examined with the utmost care by his physician, who had treated him for a long time, and an *x*-ray of his teeth showed that the root of a molar in the upper jaw—the tooth having been crowned for nearly two years—presented evidence of infection. The crown was removed, a few drops of pus escaped, and after this the patient made a somewhat rapid recovery. The tooth was treated and left

*Read by title at the eighteenth annual meeting of the American Therapeutic Society, New York, June 1, 1917.

open for a long period. The patient spoke most decidedly of the improvement in his general condition after this treatment, and he is greatly impressed with the belief that many of his former symptoms of exhaustion, and, at times, inability for prolonged exertion in his business, were due to this septic tooth. In a fairly short period his boils disappeared and there was no recurrence.

This and other cases are not presented as perhaps demonstrating a fixed principle to guide us in the study of our pathology, but as having some bearing upon our therapeutical investigations. It matters not what may be our treatment for the relief of pathological lesions, since it is becoming more and more demonstrated that bacteriological examinations of secretions and discharges, and the researches constantly going on in our laboratories, are becoming of great value, and that such thorough investigation of surgical lesions is indispensable. It reverts to the principle that settled in upon my convictions of many years, that when our patients are not recovering along such lines of treatment as we had expected in confirmation of our diagnosis, time passing, we cannot be too energetic in reviewing the situation, in going over the patient's history and symptoms. Every possible condition, such as boils, tonsils, septic teeth, various sinuses, results of old surgical lesions, or of physical ailments that may have prevailed at one time, should be investigated with the utmost care, and we must include a thorough laboratory study of the secretions from the auditory canal as well as the nose and the Eustachian tubes. In fact, no part of the human body should be slighted ere we call a consultation.

The keen, up-to-date consultant will have all the more confidence and respect for the practitioner of medicine who covers the ground so thoroughly. It may make his study of the case exceedingly difficult. He will consider himself very fortunate, when he is called in consultation with such an exact practitioner; therefore, although no hidden factor in the case be found, the consultant with a broad view of the situation will not infrequently coincide with the diagnosis, and then be able to mark out a line of treatment somewhat different; in this manner he adds much to the therapeutical atmosphere of the situation.

Our laboratory researches of to-day place us upon a more solid foundation with reference to the proper understanding of the examination of the blood, the urine, the secretions that come from mucous surfaces, and as the result of laboratory research we can readily understand certain symptoms along lines of absolute knowledge, especially in regard to the mouth. Perhaps at no time has there been a greater interest than at present in reliance upon the importance of making a correct diagnosis regarding infection of joints, in the disturbance of certain functions pertaining to the muscles or nerve centers, in going over more thoroughly a tonsil that in the past has not attracted very much attention. A more careful observation of conditions may assist materially in determining a line of treatment that will lead to recovery of the patient.

Case II.—Somewhat recently I had my attention called to a patient, a lady, act. 60, with a previous history of excellent health, who had every possible comfort, but who, for a period of two years, had suffered from supposed rheumatic conditions with, at times, a painful condition of the neck resembling incipient torticollis, with that marked lameness of the knees that led to the diagnosis of a supposed broken arch. She wore most persistently a metal support, but with no permanent improvement. Her teeth had had admirable treatment by a very competent dentist. Since she did not improve, it was suggested that a warmer climate might be beneficial. As she was leaving, her dentist advised an *x*-ray of her teeth, but this was not possible at the time. The months of change of climate did little good, so she was finally persuaded to make an extra trip in order to consult a very competent radiographer. However, before doing this, it was thought advisable for her to consult a nearby, exceedingly good dentist, for examination of what was called a double crown of the two molars in the upper jaw, the work having been done two years previously. At that time it was stated that the one tooth was not free from an ulcerative process of the root, but the root had been carefully filled, and a crown surrounding this tooth, together with the one fitted over the next tooth, which was supposed to be free from any disease, was removed. This double crown formed a bridge holding the diseased tooth more firmly, but when the dentist separated the bridge and took out the tooth that had been filled, it was found to be in a most marked condition of advanced caries; in fact, the root that had been removed was immediately recognized as the source of the secretion that had been escaping into the patient's mouth for a period of eight or ten months. At the time she thought it came from an abscess connected with the tooth, but of these conditions patients are often not so concerned as they should be.

After this treatment she had an explosion of symptoms. Her neck was much worse, and she had an acute exacerbation of pains about the knee joint, all of which improved later. But the condition of the muscles of the neck did not progress, as it was hoped. The *x*-ray examination showed that the cavity of the tooth had healed and that the adjoining tooth was in good condition. But the *x*-ray picture of the neck showed a decided spur projecting from the fifth cervical vertebra—not the development of an extra rib, but a condition that probably had had much to do with her disturbed lesions. The patient has improved, while taking treatment at one of the sulphur springs of the Middle South, increased comfort coming to her, her friends, and her physician, in knowing that a more correct diagnosis had probably been reached.

Case III.—An excellent physician of middle age, in the enjoyment of a well-earned practice, had felt, for a period of two years, a reluctance to and difficulty in doing his work, but no observations of his own nor examinations made by competent associates seemed to reach a positive diagnosis, whereby treatment granted any relief. Finally, the suggestion was made that he have his teeth examined, due, somewhat, to the fact that he had had considerable work done on them for a period of two or three years. This *x*-ray examination demonstrated that a crowned tooth had a well-marked lesion about the root. The crown was removed and the tooth treated partially. It was not filled, but an attempt was made to keep it in an aseptic condition, and in six months he was so decidedly improved that it was fair to assume the cause and effect, in that this tooth was undoubtedly septic and the absorption gave him much of the uncomfortable distress from which he had suffered.

I should say that in the former case a very careful blood examination had been made, the patient stating that nothing was found to aid in a better understanding of her case. In the latter case it was said that the result of the examination showed profound anemia.

I am speaking of these cases, not arranging them on the basis of a scientific paper, but perhaps to demonstrate that there are yet conditions where much good can be derived from a more thorough effort at diagnosis, and which, from the surgical side of our practice, really becomes a therapeutic agent.

Lesions of the joints, lesions of the muscles and of the nerves, of the various sinuses, and other regions of the body, not responding to prolonged medical treatment, eventually drift into the hands of the surgeon, or a consulting surgeon, and whenever operative intervention can be avoided and therapeutic remedies made use of it is certainly much to our credit to take advantage in that direction.

To every surgeon the secretions of the mouth have been a source of anxiety for years. One who has been in practice for any length of time will call to mind a not infrequent number of serious lesions that have resulted from puncture about the edge of the finger nail, from the bristles of a nail brush, when a rapid infection occurred, and abscesses developed along the forearm and in the axilla, requiring decided surgical operative intervention. In many of these cases the recovery was somewhat tedious, and there was a mortality list.

The surgeon of much experience will look upon these conditions with as much apprehension as he looks upon the cases of the abscess or furuncle that appears about the angle of the nostril, about the lip, or within the nasal outlet. We know how exceedingly dangerous they may be.

In the Mayo Clinics, Vol. 6, Charles H. Mayo has published a valuable paper on "Mouth Infection," referring more especially to pyorrhea and like conditions, but it requires a much more extensive study on the part of the members of our profession to grasp its full meaning. He refers to Rosenow's great work, with an indorsement resulting from a very large experience, and I make the following quotation, as it seems to be so very appropriate here: "The physicians engaged in this line of observation require fully as much training in the rudiments of dentistry as the dentist does in the signs of infectious diseases. While we have leaders in all professions, through the energy of their kinetic glands, the 'big stick' which leads to our advancement is in the hands of the progressive and educated public, who are constantly demanding more of their dentists, of the medical profession, and of the State in protecting them against preventable diseases.

In days past, when our bacteriological examinations came to us, we felt somewhat comforted when the report of *staphylococcus aureus* was obtained, realizing that the condition was not so serious as the case presenting streptococci. Now, recent laboratory investigations and the reporting of a fatality that has continued, teach us that this form of staphylococcus has a virulency that must be respected, and reached promptly when once the symptoms and examination tell us of the danger. To-day the bacteriological work is giving the surgeon the greatest help that has been presented at any time since our understanding of cultures, as well as the classification of bacilli, and association of micro-organisms. Therefore, I want to emphasize that we must encourage efforts in investigation, that therapeutical agencies must be recognized and employed to bring as favorable results as do the most difficult operations, or exhibiting our surgical skill to the utmost. As professionals we are far from being perfect in our diagnosis. Amidst all our wonderful progress in surgical work our laboratory autopsies show an unmistakable record of errors. Let us, therefore, be reasonable and sensible with one another, and, wherever possible, gain a point that will enable us to become clearer.

I think that when a surgeon has reached my time in life, and has passed through decades when nothing was known of bacteriology and laboratory research, he may, with the profoundest gratitude, refer to the advances that have come to that branch of his profession due to the pathological studies and investigations of the laboratory. And I now wish to emphasize that no surgeon can be successful without encouraging and employing to the fullest extent the aids rendered by the splendid workshops that are now in all our medical centers.

When we consider the great advances made in the last decade in the study and understanding of pathogenetic micro-organisms, there are too many fatalities, especially among the members of our own profession. In our midst death stalks, and we apparently are left helpless in the cases of septicemia that baffle our every effort.

THE EXAMINATION OF PATIENTS SUSPECTED OF BEING INSANE.*

By WM. RUSH DUNTON, JR.,

ASSISTANT PHYSICIAN, THE SHEPPARD AND ENOCH PRATT HOSPITAL.

TOWSON, MD.

The necessity for determining whether a person is insane may arise during the course of treatment of many forms of disease, for example, thyroid or Bright's; or a person who has been more or less peculiar for some time may commit some illegal act and the question of his or her responsibility must be determined.

In the first case we are dealing with a purely medical question, in the second the medicolegal status is of greater importance than the medical question of what may be done to bring about recovery. In both cases, however, the examining physician will probably be required to fill out a certificate that the patient is insane and requires treatment in a hospital specially organized for the treatment of mental cases.

On account of his knowledge of the patient when mentally normal the family physician is probably the person best qualified to judge whether his present symptoms are a departure from his normal, and should make the initial examination. If the physician is in doubt as to the interpretation of his observations and has difficulty in forming an opinion, the proper step is to call in an alienist or other consultant, and together they may make an examination and give the necessary certificate for commitment. Whenever possible, however, it is best for patients needing treatment to seek the same voluntarily. There is apt to be much better cooperation on the patient's part if he or she is able to recognize the necessity of hospital care and has been persuaded to sign a statement to the effect that he enters the hospital voluntarily. If this point has been gained he has a partial insight into his condition and has started on the road to recovery.

Voluntary admissions are quite common to many

*Read at a meeting of the Baltimore County Medical Association held at Mt. Hope Retreat, Aug. 16, 1916.

of our hospitals and sanatoria and recent legislation makes easy the admission of such cases to our state hospitals, so that probably before long the majority of cases under mental care will be voluntary. There will always, however, be a small number who must be admitted by certification or by *de lunatico* proceedings.

The first examination of such cases usually is made by the family physician, who may be untrained in the observation of mental cases. On this account he may approach his task with diffidence and a lack of confidence. I believe that this is caused to some extent by a knowledge that a complete mental examination is a long and apparently complicated affair. As a rule, so complete an examination is unnecessary to bring out the fact that the patient is mentally alienated which is all that is required for making the certificate of insanity. It is not necessary to make a differential diagnosis and state the form of alienation from which the patient may be suffering; it is necessary only to determine whether the patient is mentally normal or abnormal.

For those who feel impelled to classify their cases, I believe that it will be well if they adopt one of the oldest and simplest classifications, one which divides mental cases into mania, melancholia, and dementia. This will include all cases of excitement, depression, and weak mindedness. Expressed in other terms, but with practically the same meaning, we have cases which show a hyperfunction, a hypofunction, or a parafunction. The advantage of a classification is that by a word or two we are given a mental picture. For example, when we are told that Jones has pneumonia, we know that Jones has an inflammation of the lung with certain accompanying symptoms. Our conception of Jones' illness may also be considerably amplified if an adjective such as croupous, catarrhal, lobar, etc., is added to pneumonia. Just so, the adjective "acute" prefixed to mania, signifies to us that the patient is restless, talkative, and shows pressure of activity to a marked degree. In other words, that there is hyperfunction.

While these names are convenient for daily use, they do not indicate the degree of illness. With pneumonia, or even croupous pneumonia, we cannot form an adequate conception of just how seriously sick Jones is. Nor by the term "acute mania" can we exactly conceive the condition in which our patient may be. Hence it is better to describe the condition which we find rather than to trust to names for description.

It also simplifies the examination of mental cases if we go back to a very simple form of psychology which divides the psychic functions into three spheres: Those controlling conduct, or the will; those controlling intellect, or ideation; and those controlling emotion or feeling.

Frequently, at a glance we know whether a patient is depressed or elated or apathetic or demented. The facial expression, attitude and actions may indicate this. Experience tells us whether this emotional state may be regarded as pathological or not, so that we may have already discovered that our patient shows a disturbance in his emotional sphere without our having had any conversation with him. By the same inspection the patient's foolish actions may have given evidence of an intellectual disturbance. Inspection may have also given evidence of organic brain disease, such as paresis, by the facial expression, fixed pupils, lack of coordination, etc. This evidence, of course, must be confirmed by further examination.

A number of years ago I formulated a very brief examination to be used in the Neurological Dispensary of the Johns Hopkins Hospital. This has worked very satisfactorily, and is of special value where time is limited and the examiner wishes to reach a conclusion as quickly as possible. When the patient is quiet I often preface my question with the statement that I am about to ask him some questions which I wish him to answer naturally, even though they may appear to be foolish to him. Whether this is done or not will depend on circumstances.

What is your name? is first asked. A correct reply will indicate that the patient is oriented as to person, and is not suffering from any delusion that he is Wm. J. Bryan, or other celebrity. Even when answered correctly, a symptom may be shown; for example, we would hardly expect an adult to reply "Jack." "John Paul Jones" might be normal, or if said with a combative manner might indicate persecutory ideas; or, in a grandiose tone, might give us the key to our patient's trouble.

Where are you? The reply indicates whether the patient is oriented in place, and should certainly be answered correctly. An incorrect answer would probably indicate mental confusion, but a silly reply would be made in a case of dementia præcox.

An error of several days may be permitted in replies to the question, What is the date of today? This shows us whether our patient is oriented in time or not.

Are you sick? From this we learn of the patient's ideas of his physical condition, and often this question will open up a great many physical delusions, or ideas of reference.

Are you happy? This question is also apt to open up any delusive ideas which may be present, and a knowledge of which can be elaborated by further questioning.

Is every one kind to you? This will bring out any persecutory ideas.

Have you ever seen objects or heard noises which you afterward found were imaginary? This question may be put in a different form. The patient being asked about his dreams, and being led up, more or less gradually, to the above question; the object being, of course, to learn if the patient has had any fallacious sense perceptions; that is, hallucinations or illusions. I recall that one patient had answered all the former questions correctly, but when this one was put to him he replied that he had often heard the Lord Jesus Christ talking to him, following up which lead it was easy to bring out a number of paranoid ideas.

It should be understood that when an answer to any question indicates an abnormal way of thinking, this lead should be followed up, and the questioning on this point not abandoned until

the examiner is satisfied that upon this point, at least, the patient's ideation is or is not abnormal.

Memory should be tested by questions relating to the life of the patient, such as date of birth, marriage, change of residence or position, etc.; also by certain historical events, such as the date of onset of the present European war, the Spanish-American War, the Baltimore fire, etc. Memory may also be tested by explaining that the examiner will say three words, which he does not wish the patient to repeat to himself or aloud until the examiner asks what they were.

The words, "desk," "chair," "table," are often used, and the time when they are spoken is noted. The patient's attention is then engaged with other questions, and after two or more minutes the patient is asked what the three words were. Normal persons are able to give these three words at the end of two or three minutes, no matter how much distraction has occurred in the interim.

While the attention can be noted while the patient is answering other questions, which should be done without circumlocution or prolixity, without losing the goal idea, it is well to test the attention by the so-called "six from one hundred test," the patient being asked to subtract 6 from the 100, six from the remainder, and keep on subtractiing six from the remainder until he gets to zero. You will note the suggestion about the last, which may be avoided by saying "until you can go no further," in place of "until you get to zero." But this suggestion does no harm.

The subtraction should be done correctly, evenly, and in at least 55 seconds, even though the patient says the subtraction aloud. Pauses between the various steps indicate a lack of power of controling voluntary attention. It is interesting to note some of the remarkable results obtained with this test. Only yesterday a well-educated young woman whom I was examining gave the following answers: 6 from 100 leaves 94; 6 from 94 leaves 87, 77—no, 81, 67, 61, 57, 47, 41, 37, 31, 27, 21, 15, 10; 6 from 10 leaves 4 and nought. Eight minutes were required for the performance of this test. This length of time may indicate a degree of mental confusion or of mental weakness, as defects in the control of voluntary attention occur in these kinds of cases.

Besides the "6 from 100" test it is well to test the patient's ability to calculate and reason by a few simple arithmetical problems, such as: How much is 6 plus 2? How much is 6 minus 2? How much is 6 times 2? How much is 6 divided by 2? A further step is increasing addition, such as 6 plus 2 equals 8; 8 plus 14 equals 22; 22 plus 36 equals 58. It is better not to correct the patient if he makes any error.

I was rather surprised at the aforesaid young woman's not knowing the meaning of the word "plus," so that I had to change my question to: How much is 6 and 2? Ignorance on this point is far more common than one would suppose.

Elsewhere I have spoken of an abbreviated association test which has considerable value in giving us leads to find out what delusions may be troubling our patient. If you have read detective stories, or played parlor games, you are probably in a measure familiar with this test. The average normal reaction time is two seconds. This is best taken with a stop watch, as by it one can ascertain slight abnormalities; but a little practice with an ordinary second hand enables one to judge fairly correctly on this point. The technique of this test may be briefly stated: that the patient is told to say the first thought that comes to him when he hears the given word, the time between this and the response being noted. A delay in reaction time usually occurs when the patient has something to conceal, either consciously or subconsciously. By questioning the patient on his delayed responses it is frequently possible to bring out delusions or suppressed complexes.

The use of this test, however, brings us to the finer points of mental examination. It is rarely necessary to use it for the purpose of finding out if our patient is sane or insane.

We must not forget that a history of peculiar actions is important. It is quite proper to question our patient concerning these, and it is not unusual to find in his explanations ample reason for certifying that he is insane.

I have given you very briefly a short form of mental examination which has proved of value in determining the mental status in many cases. Like everything else, familiarity with it will increase its value to you. I trust that you will find it useful.

THE TECHNIQUE OF TRANSDUODENAL LAVAGE IN OFFICE PRACTICE WITH OR WITHOUT OXYGEN INSUFFLATION.

By M. ERNEST JUTTE, M.D.,

NEW YORK.

THE striking results obtained with transduodenal lavage, especially in conditions previously unresponsive to other forms of treatment, entitle it, in the author's opinion, to more general adoption as an office procedure. He feels justified, therefore, in supplying in this paper a demand for a more detailed description than was given in his previous, perhaps too condensed, articles on the subject, especially, too, in view of a few important novel features. The method is now so simplified that it is possible to administer simultaneously with it Oxygen Insufflation into the intestine by way of the duodenum, which is also described in the following.

Transduodenal lavage is the most effective method of removing from the intestinal tract all noxious material. It consists in flushing the bowel from pylorus to rectum in the normal direction of peristalsis, and depends for its cleansing effect upon the mechanical action of fluid in bulk.

Gross[1] in 1911 first spoke of Duodenal Lavage, meaning thereby extension of gastric lavage to the duodenum, that is, he injected water and recovered it by syphonage, and in some cases allowed it to remain *in situ* where it became subject to absorption.

Transduodenal lavage, as a method of cleansing and flushing the entire intestinal tract by means of a medicated solution designed to pass all along the bowel unabsorbed by the mucous membrane, was first described by the author.[2] Subsequently, others[3] have employed transduodenal lavage, *e. g.* Palewski,[4] who modified, though not improved upon it, and who

also describes a technique, suitable for hospital use, of combining with it oxygen insufflation into the intestine. Oxygen insufflation per se, by means of a duodenal tube. was originally practiced and described by Ad. Schmidt[5] and later by Gross.[6]

The idea of transduodenal lavage first came to the author when puzzled as to how best to empty the bowel of its fermenting, mucoid contents in a case of bronchial asthma, where he suspected absorption of intestinal poisons as a causative factor. The ultimate recovery of this case justified his suspicion; since then cures in many other ailments differing widely in their manifestations have strengthened his belief in the correctness of the arguments advanced by those who hold "autointoxication," "intestinal toxemia," "intestinal stasis," or whatever other name may be associated with the condition of absorption of intestinal toxins, responsible for many ill-understood ailments so often treated without success for the simple reason that their intestinal origin is not recognized and therefore remains untreated.

The indications for transduodenal lavage are, therefore, exceedingly wide, for besides ailments of distinctly intestinal origin, such as ptomaine poisoning, indicanuria, typhoid fever, diarrhea, enteritis, colitis, "gas," worms, many others less obviously dependent upon the gastrointestinal tract come within its scope. Among these conditions, already satisfactorily treated with transduodenal lavage are primary and secondary anemia, goitre, rheumatism, gout, arthritis, bronchial asthma, chronic catarrh of the respiratory tract, certain cases of high blood pressure, biliousness and other liver and gallbladder diseases, pancreatitis, general malaise, melancholia, neuroses, neuritis, insomnia.

Some of the considerations upon which transduodenal lavage is founded are: Laxatives and purgatives do not produce nearly the cleansing and salutary effects produced by transduodenal lavage and hence cannot take its place. The drinking of water, even in large quantities, does not flush the bowel, since the pylorus allows only a small quantity to pass through at a time. Water, also, is speedily absorbed by the intestine. Hypertonic solutions, if they could be taken by mouth, are similarly subject to pyloric control, but they are out of consideration because they are too distasteful and would not be tolerated by the stomach. Consequently, the fluid must be carried to a point beyond the pylorus, in bulk sufficient to flush and free the bowel of its noxious content, and it must be fairly isotonic, that is, of such a nature as to remain unabsorbed by the mucous membranes and still not hypertonic to such a degree as to act as an irritant to the intestinal mucous membrane.

To be suitable as an office procedure, the treatment should be fairly easy to take and must not interfere with the patient's occupation; the tube must be so constructed that it will enter the duodenum quickly and a simple method is necessary to ascertain when it has passed the pylorus. All these points are covered by the use of the author's duodenal tube, solution and test described in the following.

Other points of importance are: Concerning the patient: His stomach must be empty, since only then does the pylorus relax and permit the tube to pass into the duodenum. Therefore, the best time for treatment is before breakfast; if not feasible, he should have eaten nothing for from 5 to 6 hours prior to coming to the office.

Concerning the tube: The author's tube has at least two conspicuous advantages over all other types. First, with the aid of an obturator it can be manually introduced into the stomach. Secondly, owing to its small sinker it slips through the pylorus without delay, so that it need not remain in the stomach for hours before the treatment nor need it be retained between feedings if used for duodenal alimentation.

Concerning the lavage fluid: In a busy office it is convenient to keep a stock bottle on hand with grams 90. each of sodium chloride and sodium sulphate dissolved in 1000 c.c. of water slightly alkaline and filtered through cotton. To 100 c.c. of this solution add 900 c.c. of water at 100° to 110° Fahr. This concentration usually passes along the bowel unabsorbed, but in order to make certain it is often well to add one-half to one teaspoonful of a 10 per cent alcoholic solution of phenolphthalein, stirring the mixture to prevent precipitation en masse. This standard solution is suitable to most cases, but modifications will suggest themselves according to conditions, *e.g.* addition of quinine in amebic dysentery; salicylic acid, gram 1.0 in severe fermentation; medicinal soap gram 0.5 in disturbed fat digestion and pancreas disease, anthelmintics in intestinal worms, etc.

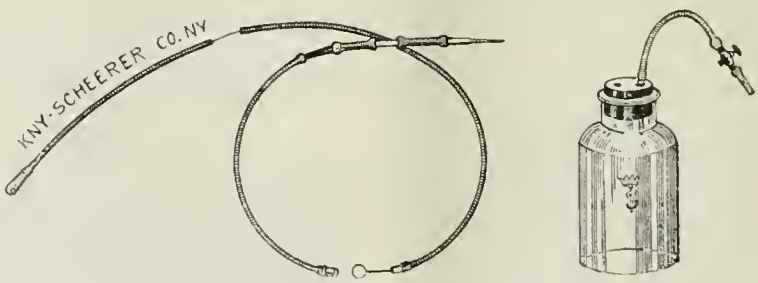

Fig. 1—Author's Duodenal Tube, with Suction Bottle

The author's outfit consists of: The duodenal tube with obturator. A bottle of glycerin and a small, all-glass hypodermic syringe for forcing glycerin into and lubricating the interior of the duodenal tube so that the obturator may be withdrawn without friction. A large all-metal syringe and a wide-mouthed four-ounce bottle with doubly perforated rubber stopper for aspirating gastric and duodenal contents, respectively; one perforation carries a piece of glass tubing two inches long, to which is attached about 10 inches of rubber tubing with a stopcock in its middle, for maintaining suction. An

atomizer with 1 per cent cocaine for spraying the throat. The stock solution described above. A 10 per cent alcoholic solution of phenolphthalein. A tapering glass tip for attachment to the duodenal tube. One or two ounces of milk to which is added a little crushed cracker.

The technique of transduodenal lavage is as follows: Prepare 1000 c.c. of the lavage fluid as above described and suspend container about 6 feet from the ground. Force a little glycerin into the duodenal tube with the hypodermic syringe and insert the obturator to bottom of the hollow stem of the sinker. Protect patient's clothing with a rubber apron and let him be seated comfortably in a chair. If he is sensitive spray his throat with the 1 per cent cocaine solution. Explain to him the steps you are going to take. Take hold of the tube about 6 inches from the end, place its tip on the back of his tongue and tell him to swallow once. This opens the pharynx and allows of thrusting the tip of the tube over the back of his tongue; then while he breathes audibly and takes occasional drafts of water gently push the tube step by step into the stomach. When down the œsophagus a few inches it is well to hold on to the obturator and to slide the tube along it until introduction is finished, when the obturator is withdrawn entirely. With care there is no gagging or appreciable discomfort.

Let him lie down on a couch on his right side. The weight of the sinker and peristalsis stimulated by the water taken, carries the tube almost at once into the duodenum. Adjust the proximal end which carries the glass tip to the suction bottle and aspirate with the metal syringe. As long as the tube is still in the stomach, only fluid of watery consistency comes up. When the pylorus is passed the return fluid begins to flow like syrup, *i.e.*, it draws out into a thread, owing to the admixture of duodenal secretion. As the fluid flows or drops down into the bottle the change from watery to syrupy consistency is easily seen. The author has found this simple working test for locating the tube perfectly reliable hundreds of times; no *x*-ray is required. At times fluid of gastric origin comes up bile-stained and may for that reason deceive the operator. At other times duodenal secretion is abnormally thin in consistency and flows almost like water. When in doubt it is well to try to stimulate peristalsis by letting the patient drink more water or to force about 2 or 3 ounces of water through the lumen of the tube. If after five minutes still no syrupy fluid is returned the tube may safely be regarded as having entered the duodenum; usually this occurs within two minutes. In hyperacidity the drinking of half a glass of water with half a teaspoonful of sodium bicarbonate dissolved in it, will quickly relax any spasm. The patient then sits up in a chair next to the irrigator stand and is given 2 or 3 ounces of milk with crushed cracker to drink; this causes the pylorus to contract and close in upon the duodenal tube, and prevents a backflow of any lavage fluid into the stomach.

Adjust the leader of the container, after draining the cooled-off fluid, to the duodenal tube in such a manner that the connecting glass tip points upward. This regulates the flow and prevents the fluid from running in too fast. The rate of flow should be a quick drip, the amount about 1½ to 2 pints, and the time consumed in running in from 5 to 10 minutes.

The rate of drip may be further regulated by occasionally turning the stopcock for one-half to one minute. This should also be done if the patient has a sensation of fullness. Very soon after beginning the lavage the patient is liable to become conscious of peristalsis and to feel or hear fluid and gas passing onward; there is no griping or discomfort at this or any other time. When all the fluid has entered the duodenum the patient is given a basin to hold and the tube is very gradually withdrawn. He can now have his breakfast. In from half an hour to two hours he has from one to three fluid, easy movements which leaves him relieved and refreshed. The whole treatment takes from 15 to 20 minutes. Sometimes useful information may be obtained by testing the aspirated fluid with litmus and congored paper.

The frequency of treatment depends on the severity of the case. In very severe cases it may be given once daily for up to 10 to 20 days; then two or three times a week for 1 to 3 months; in the average case two or three times a week for about

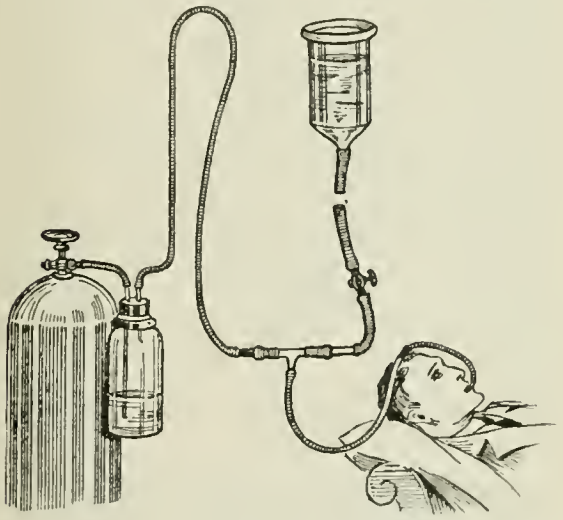

Fig. 2—Combination of (Trans-) Duodenal Lavage and Oxygen Insufflation

one month and thereafter at rarer intervals; sometimes once a week is sufficient. Each case should be treated individually, the endeavor being first to establish normal conditions in the bowel and then to maintain them by an occasional treatment until such a time as nature needs assistance no longer.

As regards oxygen insufflation, the author has not practiced it sufficiently, at this writing, to enable him to add to the existing literature by way of therapeutic results but what follows is stated because the technique employed now makes it possible to administer it together with transduodenal lavage in the doctor's office.

In adding oxygen insufflation to transduodenal lavage it is only necessary to make provision for connecting the duodenal tube also with a tank of compressed oxygen. This is done by inserting into its upper end a Y-shaped piece of glass tubing; the rubber connection between the free arm of this glass tubing and the oxygen tank should be of small caliber and be long enough to be carried to a point above the irrigator as otherwise gravity will force some of the lavage fluid into the tank.

The technique is in all respects the same as that described above except that the patient is placed on his back while oxygen and lavage fluid enter the duodenum. In this combined process it is essential that the patient take some milk or semifluid after the tube is *in situ,* as otherwise some of the oxygen will escape upward. Both oxygen and lavage fluid are allowed to enter simultaneously, the rate of influx being easily controlled by the operator who manages valve and stopcock as occasion demands. The duration of this procedure depends upon the amount of gas that it is desired to introduce. Four quarts are easily borne. Gross states that Ad. Schmidt is in the habit of giving daily oxygen insufflation lasting from half to one and a half hours. There is moderate distension of the abdomen. A good deal of the oxygen is absorbed; the balance is passed as flatus. Both objective and subjective results of oxygen insufflation are very striking, especially in fermentative and putrefactive dyspepsias and catarrhs.

A NEW METHOD FOR THE DETERMINATION OF GLUCOSE CONTENT IN URINE.*

BY J. J. GURTOV, M.D.,

NEW YORK.

GLUCOSE in solution is quantitatively determined in one of three ways, viz., the gravimetric process, the polariscopic, and the volumetric method or titration. Of the three the gravimetric is most accurate, the volumetric the least accurate. For various reasons glucose in urine is almost exclusively estimated by titration. The reagents for this purpose commonly consist of copper sulphate in solution of some alkali. The main fault of the older reagents is that they reduce other substances in the urine than glucose, they deteriorate upon standing and are not sufficiently sensitive. In 1911 Benedict (*Journal A. M. A.,* LVII, 1193) described a method for estimating glucose in the urine, in which all of the above faults were largely eliminated. The investigation of Maclean (*Biochem. Jour.,* 1907, II, 156) and Benedict (*Jour. Biol. Chem.,* 1907, III, 101) have shown that copper sulphate solution in alkali with a hydroxide radical lose their reducing power toward glucose if the titration is to be continued for any length of time. Such reagents also reduce other substances, as creatinin aldehyde, chloral, uric acid, etc. Whereas if the hydroxide radical is replaced by that of a carbonate, the reducing power is not interfered with and is not affected by other substances than glucose. But there is one very important defect common to all reagents, and that is the difficulty of determining just when the end reaction takes place. In the reagents referred to, the blue color of the copper sulphate serves as an indicator and the end reaction is shown by the disappearance of the blue color.

This is a very uncertain factor, as it varies with a number of circumstances, is dependent upon personal equation, and is therefore a source of great error. Thus, in the original Fehling's the red oxide so much obscures the blue color that it is practically valueless for quantitative work. One of the earliest attempts to obtain a definite end point was to moisten a white piece of filter paper with a solution of ferrocyanide, the titration being continued so long as a drop of the reagent transferred to the cyanide paper gave a brownish color. The procedure was as inaccurate as it was tedious. Numerous modifications have since been made by Purdy, Rudisch, Pavy, and others to overcome this difficulty, as for instance by the addition of ammonia to dissolve the red precipitate, or as in Benedict's reagent the red oxide is converted into white thyocyanate. But in all those reagents the recognition of the end point is a matter of some difficulty. For at the time the blue color is discharged the resulting solution is not colorless but has a brownish tinge, due to the carameling of the glucose with the alkali as well as to some elements in the urine. The difficulty of recognizing the disappearance of the blue color is thereby accentuated; and although the white thyocyanate somewhat lessens this difficulty it does not entirely eliminate it. The illumination of the room is also not an important factor in titration; for unless there is a perfectly good light the transition of color is not readily noticed and will be a source of error. It is here too that personal equation enters as an element.

In the new method the end reaction does not depend upon the disappearance of color but upon the appearance of a precipitate. The principle of the method is based upon the fact that copper sulphate in alkaline solution is reduced by glucose to copper oxide. If a solvent (in this case potassium ferricyanide) be added to the solution in an amount less than is necessary to dissolve all of the copper oxide the reagent will remain clear throughout the titration until all of the cyanide has combined with tne greater part of the oxide when precipitation will take place, which will indicate the end reaction. This precipitate may be made to occur at any desired point of the titration and serve as a standard of measure.

It was noted, however, that with aqueous solutions of glucose or diabetic urines highly diluted the precipitate was rather faint, whereas with urines of low dilution the precipitate was bulky. It became evident, therefore, that some substance in the urine is responsible for the nature of the precipitate. Accordingly, each of the solid ingredients of the urine has been investigated to ascertain the

*Read before the Bronx County Medical Society, May 16, 1917.

particular substance. To an aqueous solution of glucose uric acid, the urates, phosphates, and sulphates have each been added separately, but without any effect. On addition of sodium thyosulphate the precipitate became more profuse, filling the whole volume of the fluid. This makes the end point very sharply defined.

Composition of Reagent.

	Gm. or c.c.
Copper sulphate	10.0
Potassium ferricyanide	1.9
Sodium thyosulphate	1.5
Sodium carbonate	240.0
Sodium citrate	240.0
Distilled water to make a total volume of	1,000.0

The copper, cyanide, and thyosulphate should be weighed very accurately. Dissolve the carbonate and citrate in 700 c.c. water by the aid of heat and filter. Dissolve the copper sulphate in 75 c.c. water and add gradually to the other solution with constant stirring. The cyanide and thyosulphate are each dissolved separately in 30 c.c. water and added to the rest, then enough water to dilute exactly to 1000 c.c. The estimation of glucose in the urine is then conducted as follows: Dilute the urine as described below and fill the burette to the zero mark. Into a test tube 15 to 20 cm. long, measure accurately 10 c.c. of the reagent and 3 c.c. water. Add a small piece of pumice stone to prevent spurting. The reagent in the test tube is brought to boiling over a naked flame and the test tube is then placed over an asbestos wire gauze (similar to a porcelain dish) and its upper end is held by a burette holder directly under the burette; the flame is so adjusted as to keep the reagent at steady boiling. The diluted urine is now run in a few drops at a time, at intervals of about a minute, when the reagent has become considerably paler, the urine is added 2 or 3 drops at intervals of 20 to 30 seconds. As the titration proceeds the blue color will almost or entirely disappear, the reagent remaining clear and transparent until the end reaction is about to take place when it will become suddenly turbid, the turbidity deepeninng rapidly, and the whole volume of the reagent filled with a bulky precipitate.

One c.c. of the reagent is reduced by one mg. of glucose. The calculation of percentage is made according to the formula $\frac{n}{x}$ in which n equals the number of times the urine has been diluted, and x the number of c.c. of diluted urine necessary to reduce 10 c.c. of the reagent. If to 10 c.c. urine, 40 c.c. water has been added (*i.e.*, diluted 1:5) and of this 4 c.c. was required to obtain an end reaction then $\frac{n}{x} = \frac{5}{4} = 1.25$ per cent. glucose content.

As the reagent is specific for glucose it may also be used as a qualitative test. Five c.c. of the reagent are heated to boiling and 0.5 c.c. urine added, then again boiled vigorously for one to two minutes. In the presence of glucose a yellow precipitate will form.

In conducting the titration with the reagent here described two important factors must be borne in mind, viz., the time of boiling the reagent after each addition of urine and the degree of diluting the urine. As to the boiling no arbitrary time can be fixed, but by referring to the chemical reaction this may be readily judged. It will be recalled that after each addition of glucose solution there is a tendency for a precipitate to form, which dissolves in the ferricyanide upon *boiling;* the more glucose is added therefore the longer the boiling is to be continued. This point will be made more clear in connection with the second. A preliminary titration should be made with the original urine to ascertain approximately the strength of glucose. The urine is then diluted to make a glucose content of 0.5 per cent. or less. The time lost in the preliminary test is only apparent as the second titration can then be done carefully and accurately at the least expenditure of time. Supposing the preliminary test shows a glucose content of 3 to 4 per cent. The urine may then be diluted 1:10. It will be at once apparent that it will take about 3 to 4 c.c. of this diluted urine to reduce 10 c.c. of the reagent. About 2 c.c. of the urine can be run in at once and the reagent boiled for one minute or even two. The rest of the urine may then be added 2 or 3 drops at a time at intervals of 20 or 30 seconds, and this is to be continued until the precipitate appears.

To the experienced laboratory worker these explanations may he superfluous but the novice and those of less careful propensities may meet with confusion if the above remarks are not heeded. The method is very simple, rapid, convenient, and accurate. But some familiarity with the behavior of the reagent is essential to obtain the best results. Its sharply defined end reaction eliminates many sources of error inherent to other forms of titration. The following table shows to what extent accuracy in this method has been obtained.

Sample of Urine	Gravimetric Method	Polariscope	New Method
1	0.996	....	1.00%
2	0.90	....	0.84%
3	...	0.228	0.22%
4	...	0.373	0.40%
5	1.23	....	1.20%
6	0.37	....	0.40%
7	4.93	....	5.00%
8	1.00	....	1.00%

As the table shows, the new method approaches the gravimetric process not approximately but absolutely. In the construction of this table I am highly indebted to Mr. D. Chercass for his valuable assistance in making the comparative tests with the gravimetric process and polariscope.

SOME ANCIENT HEALTH LAWS OF THE JEWS.

By JOSEPH H. MARCUS, M.D.,

Atlantic City, N. J.

Attending Physician to the Jewish Seaside Home.

The preservation of physical well-being was looked upon in Judaism as a religious command. "And live through them but not die through them" was the principle applied to all the laws of the Bible, from which the rabbis deduced that in case of danger to life all laws except those against idolatry, adultery, and murder might be violated. The neglect of one's health was regarded as a sin, and the Nazarite who vowed to abstain from wine was considered a sinner, as well as he who fasted or underwent other penance without reason. Purity, which was the aim of most of the biblical sanitary laws, was to be not only physical, but also moral.

There was not a distinct department of public health in the government of the ancient Jews. The charge of infectious diseases, such as leprosy, and of epidemics of all kinds, was delegated to the priests, who acted as physicians. In later times every town counted among its permanent officials a physician who supervised the circumcision of children and looked after the communal well-being. A scholar was forbidden to live in a city where there was no physician. The rabbis have various laws regulating diet. They enjoin also divers precautions, many of which go to improve the physical welfare of the community. Special emphasis was laid upon early breakfasts. No one should force himself to eat; he should wait until he is really hungry, not hurry his meal, and not talk while eating. The rabbis even prescribed the kind of food men should eat, and that from which they should abstain, wheat bread, fat meat, and old wine being recommended as the most wholesome. Salt and hot soup are pronounced to be essentials of a meal. "After all solid food, eat salt, and after all beverages drink water," is the advice of the rabbis.

For domestic sanitation, the commandments given in the Bible direct the covering of the blood of a fowl or a wild beast with dust, and the covering of excreta with earth, and the appointing of a special place outside of the camp for the depositing of the excreta. The rabbis forbid the erection of tanneries or the establishment of cemeteries within fifty cubits of the city limits. To deposit carcasses within that distance was also forbidden. Tanneries even beyond that limit could be built only to the east of the town, so that the west wind might dispel the bad odors arising therefrom. The thrashing floor must also be removed fifty cubits from the city, on account of the chaff and the dust coming from it. It was suggested by some scholars that perpetual fires be kept up in the valley of Hinnom, outside of the gates of Jerusalem, for the purpose of consuming the refuse of the city, thus disposing of all the offal in order to preserve the health of the city. In order to prevent the spread of leprosy, a complete system of quarantine laws was developed in the Levitical code. The numerous laws of purity scattered throughout the Bible, especially in Leviticus and Numbers, were probably not intended primarily as health laws. The rabbis built up a complete system with regard to things clean and unclean upon these laws. All these laws may be conveniently divided into two classes: (1) Those which govern cases of impurity created in the body of a person, as leprosy, unclean flux of man or of woman, menstruation, etc., and (2) those which govern cases of impurity caused by contact with unclean objects, as contact with a dead body or with a person of the former class. By the careful isolation of such persons and objects and by the complete system of baths and ablutions provided by the law for their cleansing, the chances of the propagation of infectious diseases were much decreased. The rabbis regarded the laws of health as of greater importance than those which were of a mere ritualistic character. "You have to be more careful in cases where danger is involved than in those which involve a mere matter of ritual." On account of danger it was forbidden to eat the meat of an animal that had eaten poison, or to eat meat and fish together, or to drink water left uncovered over night. It was considered dangerous to drink water at the beginning of the seasons. In many places it was customary to place a piece of iron on all articles of food at that period. This was supposed to remove the danger. In time of plague the rabbis recommended staying at home and avoiding the society of men. Perspiration was considered especially dangerous, and it was therefore forbidden to touch, during meals, any part of the body which is usually covered or to hold bread under the arm, where the perspiration is usually profuse. Coins should not be placed in the mouth, as there is the apprehension that they have been touched by persons suffering from contagious diseases. Articles of food should not be placed under a bed, because something impure might fall on them. It was also forbidden to eat from unclean vessels, or from vessels that had been used for unseemly purposes, or to eat with dirty hands. These and many other laws are derived by the rabbis from the expression, "and ye shall not make your souls abominable." The washing of the hands and of the face in the morning and, according to some, in the evening also, and the washing of the hands after relieving nature were considered important, so that a special blessing was pronounced after each ablution. The rules concerning the washing of the hands before meals occupy a considerable portion of the ceremonial law, and minute regulations were prescribed as to the manner of pouring the water, the size of the vessel employed, and the kind of water to be used.

The system of baths and ablutions, which forms a large portion of the Jewish law of cleanliness, and which is still observed to a large extent by pious Jews, had a marked influence on their physical health, so that in epidemics they have frequently been immune. Provisions were also made by later rabbis with regard to sleeping. They warned against eating heavy meals immediately before going to bed, and approved first of lying on the left side and then on the right side, this being considered good for digestion. Maimonides lays down certain regulations by which man should be guided at sexual intercourse in order to preserve his physical well-being, and he promises him who complies with these precepts that he will be well, need never consult a physician, and will live to a good old age.

There are some laws whose purpose it is to prevent any cause of injury to others as well as to oneself. One who builds a new house must erect a battlement around the roof, so that no person shall fall from it. The battlement must be at least ten "fist-breadths" in height, and must be well constructed, so that one may lean upon it without apprehension. To guard against an injury one must not leave a well or a pit on one's premises uncovered, nor must one keep a vicious dog or a broken ladder. It is forbidden to walk alone at night; to stand under a wall that is likely to fall; to walk upon a poorly constructed bridge; to enter a ruin, or to drink in the dark from a well, lest some poisonous animals lurk in the water. He who defies the law saying, "It is no one's affair if I wish to expose myself to danger" is punishable with stripes, for life is considered as belonging to God and not to man.

Military Medicine.

THE WAR AND VENEREAL DISEASES.

By E. KILBOURNE TULLIDGE, M.D.,
ASSISTANT SURGEON, U. S. NAVY.

THE sanitary problem of venereal diseases should at the present time demand wide consideration. The importance of the subject is most vividly and urgently emphasized not only by the ravages which these diseases have produced among the laity during peace, but by their great increase among the troops in time of war. The scanty attention they have received in this country has been due, I feel sure, less to the ignorance of their importance than to the deliberate refusal to deal with them. The knowledge that next to tuberculosis, syphilis is the most dangerous scourge of the human race seems to be gradually making its way into wider circles and there is now hope that this hitherto much neglected menace is becoming appreciated. Since the beginning of the war England, Germany, France, and Italy all seem to have awakened from a lethargy extending over a period of many years, to the fact that these diseases must be considered and considered carefully with the same thoroughness and promptness that are exercised in regard to other infectious diseases.

There is no doubt that syphilis, gonorrhea, and chancroid never would have obtained the proper and necessary publicity were it not for the fact that this great war is causing these diseases to spread throughout the various countries involved with greater rapidity than normally. However, the worst is yet to come. What may seem a menace today in Europe will develop to become a collosal scourge in our own country when the war is over and the men come back from the front. That this fear is well grounded may be shown by what followed the Crimean and the Napoleonic wars and the statistics compiled in the various countries of Europe both before and after these conflicts regarding venereal infections. The present war has produced reports along this line that far exceed those of the past. E. Gaucher in the *Bulletin de l'Académie de Médecine* of Paris emphasizes the extraordinary prevalence of gonorrhea and syphilis in both men and women since the beginning of the war, and states that he has been appalled at the ignorance of the dangers of these conditions, revealed by inquiry among the young men of the army and navy.

Many are the lessons we have learned from our European neighbors in connection with the present war and many of them have we digested, developed, and put into actual practice. Some there are still, however, that need attention and would receive it were it not for the flimsy curtain of mock modesty that seems to have blinded us in the past. This barrier must now be broken down and thrown aside and the press of the country urged to help us to remove it. The supreme law that has facilitated so many decisions in the course of the war must prevail here also—health is a public matter. The health, sanitation, and comfort of the soldier and sailor must be of first consideration and the cooperation of the military and civil authorities perfected to that end. There is no time to spare if we expect to produce and keep physically perfect men. We are already at war. Thousands of men are under mobilization and the work should be begun. It is a stupendous job, but not too large a one for us to undertake. The number and prominence of the many authors from the various armies engaged in this great struggle who have written upon the subject of venereal diseases in the army and navy will attest the importance of the subject from the standpoint of military efficiency. We have only to review the surprising statistics compiled by Gerrish, who in 1911 estimated that 10 per cent. of the population of New York City were syphilitic and that over 18 per cent. of the people of the United States showed signs of the disease, to realize one of the vast undertakings in the hands of the medical profession upon our entrance into the war. Today syphilis has increased, probably doubled, certainly not diminished, as no precautions have been officially taken to check it. In the army not long ago Bartlett found 10 per cent. of one command infected, and Archibald Church, in a very interesting and instructive article, estimated that there were twenty million syphilitics in the United States, with an expenditure of over eight millions for the care of luetic insane alone. If we compare the statistics of Pilcz, who found that during 1890 there were 70.64 per cent. of four thousand one hundred and thirty-four officers in the Austro-Hungarian army who either died or were permanently incapacitated, were syphilitic, with a report published from the Surgeon General's office of the Royal and Imperial Army during the present war which stated the number of cases of this disease found among the officers of the same army to be 78 per cent., it is easy to calculate its steady increase despite the modern methods of treatment.

British authorities state that venereal diseases are the cause of more hospital admissions among the soldiers than any other disease or group of related diseases, causing 38.8 per cent. of the total inefficiency of the British armies in France and one-third of all illness of the British navy, both at home and abroad during 1911. V. L. Kellogg states that in 1910 the British Naval Force included 113,530 men, of whom nearly 15,000 were ill from venereal diseases and that hospital admissions of soldiers for these diseases averaged more than 1 case for every 5 men in that branch of His Majesty's service.

With these figures of one of the highest morally rated armies before us shall we hesitate immediately to consider and take hold of this stupendous problem that may place us, if left alone, far below the efficiency rating among world powers that we now hold. There is no doubt that this country, if it wishes to keep abreast of its present excellent sanitary and health status, will find itself compelled in the near future to combat syphilis as secondary to no disease other than tuberculosis, and its imperious duty will be to restrict and control its devastating action on the strength of the nation.

We must bear in mind that it is not only a question of the present health of the sailor and soldier at sea and in the field, but of the prevention of all the misery that must necessarily follow for the family at home. A brief résumé of the venereal records of the militia during their mobilization recently on the Mexican border will disclose that

notwithstanding the excellent prophylactic treatment afforded them by the Medical Corps of the Army, many acquired all three of these well known infections to a startling degree, and had it not been for the plentiful supply and compulsory use of the prophylactic furnished them and the semimonthly talks or lectures as to the seriousness and fatality of these infections by the regimental medical officers, many more would have become victims of their indiscretions.

A complete and careful examination and inspection of over six thousand men, under my care in the Austro-Hungarian army revealed conditions that proved of startling significance. Primary lesions were found upon almost every part of the body, the palms of the hands and soles of the feet not excepted. Over 60 per cent. of the discoverable lesions, the diagnosis of which was substantiated by a Wassermann reaction, had not been reported nor had an application been made for treatment. Many of them did not know or realize the severity of their infections, and were astonished to hear of the results that were sure to follow if treatment was withheld. Few men there are, either sailors or soldiers, who suffer from venereal disease by choice, owing their malady in many instances to ignorance and the lack of proper instruction, supervision, and care by the higher authorities.

The medical and surgical officers of the ship or regiment should constantly bear in mind that if they wish to keep their men up to the top-notch of efficiency they must keep them free if possible from these too easily and quickly acquired infections. No prudery should be allowed to prevail in so doing. Provision should be made to facilitate in every way the furnishing to the men of preventive means and measures to help this end. New bodies of men or recruits should receive thorough and complete instructions upon the subject and old members of the service should be constantly reminded of their dangers. The men should be told of the great danger that every intercourse with a prostitute brings with it, a fact that many fail to comprehend. Warning signs or placards should be hung about in the barracks, hospitals, and other quarters and prophylactic measures and appliances should be placed at the disposal of the men. Not only should this be done, but each and every one should be compelled, after illicit intercourse, to take and apply a protective prophylactic treatment. Of course there are some who consider this practice and advice repugnant on so-called moral or ethical grounds, but if they will but consider seriously the dependence upon good sanitary and hygienic conditions of the welfare of their troops in the field and at sea, among whom health plays the most prominent part, they must agree that this practice is a most promising measure in obtaining results.

The best results may be obtained in the service by, first, careful supervision and frequent inspection of the men with the establishment of a severe penalty for failure to administer the prophylactic provided; secondly, providing carefully inspected, restricted, districts or houses of prostitution conducted especially for the men in the service under military supervision. This practice is successfully employed in Italy, Germany, Austria, and but lately in France and England with surprisingly satisfactory results. With the establishment of these houses during the course of venereal inspection of the men, which was held in the German army religiously every two weeks, the appearance of any venereal disease could be traced directly to the seat of infection and the prostitute placed under arrest and sent to a government hospital, where she remained until pronounced cured. For those living at sea on board ship the establishment of such districts or houses would prove a godsend for the men given liberty on shore, and would with the prophylactic almost eradicate the disease from the naval service.

Not only could steps be taken to safeguard against these diseases in the service, but proper facilities and treatment without cost should be placed at the disposal of the public at large. This is being done today in England and a few of the European countries.

The following are the details of the newly enforced scheme of the British Government toward this end.

Hospitals are established, especially at naval stations or bases, where treatment is carried out under the direction of a trained medical officer. The clinic is opened at least three afternoons and evenings each week and a stated time designated for the treatment of males and females. There is provision for six beds for each sex and the treatment will be absolutely free to every patient without distinction. Laboratory facilities are installed for the examination of all specimens and the performance of the Wassermann test. The station with its equipment is open for the use of all physicians in the district without cost. Salvarsan, neosalvarsan, and mercurial preparations are furnished for the use of all physicians gratis, and the strictest confidence is observed in regard to all persons receiving treatment.

Such clinics could be established in this country under State or municipal control, not only in the large centers, but in the small ones as well, and instruction given at them to the practitioner, student, and public at large in the care and treatment of venereal diseases.

Two prophylactic treatments for these diseases have received wide attention and consideration. The former Army "K" packet, containing a solution of 20 per cent. protargol or 10 per cent. argyrol, a medicine dropper or syringe, and a vial of 30 per cent. calomel ointment, was effective when used not only as a prophylactic, but within two hours after intercourse. In a section of over seventeen hundred militiamen who received this treatment properly on the border during the last mobilization, thirty-eight developed venereal diseases. Ten were primary luetic sores, ten chancroids, and the remaining eighteen gonorrhea which was complicated in seven cases with one of the former infections. With these results this treatment could hardly be called successful and the large percentage of infections resulted either because of the failure of the men to apply for the treatment within the prescribed time after intercourse or because of the failure of the ointment to come up to its declared standard of efficiency. With these possibilities in view and with the idea of providing for the men in the naval service who are unable to obtain treatment within the prescribed two-hour period necessary for proper results, Surgeon Robert A. Bauchman, U. S. Navy,

after an exhaustive investigation and experimentation, both at home and abroad, prepared an ointment similar to Metchnikoff's preparation, but which Metchnikoff himself declared to be a great improvement over his own original preparation in the treatment of syphilis. This ointment, which contains 33 per cent. calomel reinforced by 1 per cent. trikresol, he placed in a collapsible tube carefully prepared and enameled throughout inside to prevent a degeneration of the mercurial substance by contact with the metal of the tube itself. A soft rubber tapering nozzle one and one-half inches long, which may be introduced well up into the meatus beyond any possible area of infection, covers its mouth. This preparation he claims is most efficacious, and from the many reports of trials given it and the excellent results obtained in cases in which I have recommended its use, I am convinced that it has decided advantages over all other prophylactics of its kind at present in use. It is smaller in bulk, more compact, and therefore more easily handled. If carried upon the person at all times and properly used both before and immediately after intercourse, or within an hour, it has decided advantages over all other treatment.

EFFECTS OF POISONOUS SUFFOCATING GASES ON THE NERVOUS SYSTEM.

Of a symposium of five articles on gassing, in *Russkii Vrach* for May 6, 13, and 20, no less than three are devoted to the effects produced on the nervous system. Neiding and Serjesky write on the general subject, while Lenorsky devotes his paper to the effects of gassing on the vegetative nervous system. So fas as we know, no description of gas poisoning on the Western front has laid any emphasis on nervous manifestations in this connection, nor has it been claimed that any of the gases in common use have special neurotropic activities. Even in Professor Boldyreff's general survey of the treatment of gassing we find no special reference to nervous manifestations. Neiding had had under his care some 274 victims of gas poisoning. This material shows no evidence of selection of any kind. Eliminating cases without nervous symptoms, or with but a single nervous manifestation, there remained 136 patients with two or more manifestations which would place them fairly in the category of nervous subjects. In 26, these manifestations were all objective, the balance presenting subjective or mixed symptoms. For example, 10 patients complained of headache and vertigo, and were analgesic, while 37 presented pupillary anomalies, heightened reflexes, and analgesia. Absence of the pharyngeal reflex was frequently encountered.

In a few cases there were noted lesions of the eye and ear. Generally speaking, the symptoms suggest, in part, those seen in traumatic psychoneuroses, and to this extent present no evidences of a specific neurotropic action. However, two factors are clearly in evidence, the author believes, to wit: psychogenic and neurotoxic.

Serjesky, in his paper, deals largely with the last-named factor. He concludes that the gases are incidentally nerve poisons, and that this toxic action is especially in evidence when an hereditary neuropathic taint furnishes a favorable soil. He enumerates the following nervous symptoms: Headache, vertigo, mental and physical weariness, retardation of all neuropsychic processes, impaired memory and attention, etc., not unlike the symptom picture of cerebral arteriosclerosis in its earlier stages. Certain patients complain of tinnitus aurium. Both simple neurasthenia and hystero-neurasthenia are represented in the material. The evidence of a somatic factor seems indirect, based on certain analogies between the sequelæ of gassing and those of carbon monoxide poisoning. It is also possible to isolate a purely exogenous type in those without predisposition, and an endogenous type in which the neuropathic substratum is in evidence.

The most elaborate study by far is that of Lenorsky on the action of the poison gas on the vegetative nervous system. He finds that vagotonus may be present in one or another stage of the disease, and that in certain cases there is an increase in the tonus of the sympathetic. Mixed forms are encountered, and a certain amount of dissociation.

LETTERS FROM AN M. M. R. C.

If I were asked by the Surgeon General's Office at Washington, D. C., what the results were of mature deliberation after my two months of intensive training, I would without hesitation give the following criticism: Assistant instructors taken from the rank of officers of the Medical Reserve Corps are very weak reeds to lean upon. I have in previous letters suggested that not all of the instructors of the regular medical corps were quite adapted to their tasks. Apparently the fundamental and most important teaching in the Medical Officers' Reserve Camp is the knowledge of the drill manual and second in importance a practical method of acquiring proficiency in the paper work that is required by the service for its continuation along the lines now laid down.

If the army intends to teach a bunch of "rookies" how to drill it puts the detachment in charge of a non-commissioned officer, a sergeant. The latter individual may be a little rough in his mannerism, but he does know how to teach men how to drill. He will accomplish results in a short order of time that the ordinary commissioned officer would strive ages to accomplish. The doctors have to be taught how to drill. Why would not this be more thoroughly accomplished by a sergeant that knows the game from A to Z than a regular medical man who only knows it at best by snatches? Now when you come to take away the regular army doctor as instructor and in his place put another doctor as assistant instructor who has had only indifferent instruction himself, a state of affairs is created that is far from satisfactory from the standpoint of the manual of drill. Few assistant instructors agree on how certain formations should be accomplished. It is bad discipline for the private officer doctor in the ranks to have a command given and find that it was either a command impossible to give and have carried out under the condition or else this faulty command was allowed and its impropriety passed upon as being all right. There are certain orders that a column formation

can not carry out until this column is rearranged to permit its accomplishment.

The question is often asked by the inexperienced "What is the necessity of a doctor knowing how to drill?" The answer is this: the army doctor will sooner or later have a detachment of enlisted men under him. They will be men of the hospital corps. These men are trained to move together only under orders, and if their commander does not know the proper commands and how to execute them himself he will be of no use in his position. These orders not only pertain to marching formation but to the carrying of litters and pitching tent. The sanitation of the camp will come under his responsibility and also its policing as far as the medical quarters are concerned. By police duty is meant street cleaning. Every morning in camp a squad of thirty or forty men is sent out with a medical officer and it's for him to see that everything is cleaned up. He will take this detachment out at seven o'clock in the morning and will go over the section of the camp he is responsible for with a fine-tooth comb. Scraps of paper, burnt matches, cigarettes and cigar butts will be cleaned up by his detachment. Manure in the company streets, straggling sticks of wood, newspapers, and tin cans will all be eliminated, destroyed, or placed in proper receptacles. Ditches and sewers that are not draining properly will come under the care of this detachment. When they start off a few will provide themselves with brooms. There will be a few shovels in the lot and several burlap bags to hold the trash. Needless to say if this were not done every day a camp would soon become an object lesson in filth.

So much for the necessity of knowing how to give orders to your men. Now to come to the practical application of drilling as seen in the medical officers' training camps. As soon as a doctor arrives at one of these camps he is assigned to whatever company is comparatively new and where there is room for him. Each company consists of about a hundred men and they will occupy two barracks. Each company has a captain over them—usually an old man of the Medical Reserve Corps. By old, I mean one who has had about two months' experience in an officers' camp. He is the one who is going to take charge of all drilling instruction. There is little or no affiliation between different companies in the Medical Officers' Reserve Corps. Each company messes alone, has its own latrine and bath house, and drills alone. This makes it perfectly possible for a faulty drill master to bring up his entire flock of a hundred so that they will not be the wiser of their mistakes till they come among others. The only time that any of these men meet on the same grounds is during some grand parade which is but momentary and each company is only engrossed in acquitting its own duty well. Each company has its own individual lecture hour and as much clannishness is evidenced in social intercourse as between the regular army instructor and the assistant instructor from the Reserve Corps. The regular army instructor wears a white band around his hat so that he may not be confused with the assistant who wears a blue band. It is by these shades of differences that all army life is regulated.

A second fundamental criticism with suggestion that might well be made to those in authority, is that there should be a sufficient quantity of the regulation blank forms for the different kinds of paper work required by the medical department of the army, and part of the training course would include the proper making out of these papers. In actual army life most of these papers are made out by the sergeant of the detachment and the officer has only to sign them. So long as the officer is the responsible party it is absolutely necessary for him to know whether these papers are made out properly or not. He can gain this information only by practical experience. At the present time only the theory is taught. Each company should be shown how to make up its daily sick book, hospital records, muster roll, pay roll, requisition of supplies, and the many other set forms of conducting the business of the army. In this matter as in the drill, each company would accomplish more in a shorter space of time if they were under the tutelage of an experienced sergeant than they now receive at the hand of an assistant instructor who knows little or nothing about the practical end of the paper work. Continuing on this same line of criticism, it would seem to me better if the classes in French were taught by a regular teacher—there must be plenty in the country—rather than by volunteer French scholars taken from their own company.

One of the most frequent causes of discontent among the senior officers of the Medical Reserve Corps is the uncertainty as to their future movements and assignments when their course of instruction is completed. Barracks should be swept clean of old men before the new ones enter. It certainly gets on the nerves of the former to have a new bunch come into the barrack and start at the beginning again. Some wait one and two months expecting a governmental assignment of post daily. The work that was formerly pleasant and entered into with zest becomes irksome and they are apt to perform it indifferently. This situation is as bad for the new men as it is for the old. All the men should be put on some active form of duty and responsibility, if only temporary, till their final orders come from Washington.

Reconstruction Hospitals.—Surgeon General Gorgas announces that sites have been selected for orthopedic war hospitals in nineteen cities of the country. These institutions will be for the care and training of crippled soldiers who may be injured in the European war. Orthopedic base hospitals will be established near the front, where early treatment of ankylosed and injured joints will be given, and the hospitals to be established in this country will be more especially for the industrial training than for the surgical treatment of the crippled. The men will be reeducated to their former trades when possible, or will be taught new trades, to which, because of the nature of their mutilations, they may be better adapted. Workshops will be provided at the hospitals and arrangements will also be made with outside industries whereby more elaborate methods of training may be carried on. An employment bureau will be established to place men so trained. There will be accommodation at first for 500 men at each hospital, but provision will be made for enlarging their

capacity to 1000. The following are the cities where these hospitals will be located: Boston, New York, Philadelphia, Baltimore, Washington, Buffalo, Cincinnati, Chicago, St. Paul, Seattle, San Francisco, Los Angeles, Denver, Kansas City, St. Louis, Memphis, Richmond, Atlanta and New Orleans. Those in Boston, New York, Washington, and Chicago will probably be constructed first.

Gas Defense Service.—The Army Medical Department has been charged by the Secretary of War with the duty of supplying gas masks and other appliances for the protection of the United States troops against poisonous gases used in warfare. The Surgeon General has pointed out the needs of that service for a competent enlisted personnel. About fifty men are wanted immediately in mechanics, pipe-fitting, carpentry, blacksmithing, and chemistry. Those who are found qualified will be enlisted in the Sanitary Corps for the duration of the war. The following officers of the Medical Reserve Corps have been relieved from duty at the training camp at Fort Riley, Kansas, and ordered to report to the commanding officer at Fort Sill, Okla., for a course of instruction in gas defense: Captains, Felix E. Ashcroft, August A. Gossow, Rutherford B. Irones, Nevin D. Ponitus, Chelsea C. Pratt, Fred E. Sprague, John S. Sweeney, and Henry C. Woltman; First Lieutenants, William M. Bane, Carl L. Barnes, Bret Bates, Francis S. Furman, and Daniel Grant.

Red Cross Standardizes Dressings.—The American Red Cross has sent out five hundred thousand copies of a new manual giving instructions in the preparation of surgical dressings. The manual was prepared by Dr. John A. Hartwell of New York and a committee of surgeons, nurses, and lay workers. The directions are based on the most recent hospital experience both in this country and in the war zone. These standard dressings are now needed in large quantities, and many chapters are increasing their output by using power machines for cutting materials.

Special Red Cross Commission for Belgium.—A special department has been formed by the American Red Cross Commission to France to direct the relief work in Belgium. Dr. Ernest P. Bicknell, formerly director general of Civilian Relief of the American Red Cross, and now deputy commissioner to Europe, is to have charge of the work in Belgium, assisted by the Rev. John Van Schaick of Washington, D. C. Major Murphy recently made a tour of inspection behind the Belgian lines and laid out a program of relief to include financial assistance to the Belgian hospitals and for the care of between five and six thousand Belgian children in cooperation with the Rockefeller Foundation. The work is to include reconstruction and rehabilitation of villages recovered from the Germans.

Gifts to Red Cross.—The parishioners of St. George's Church, New York, have presented the Red Cross with an ambulance which is to be sent to France at once. Efforts are now being made to interest the Protestant Episcopal churches in the diocese of New York in a fund with which to send army kitchen trailers to France. Madame Alma Gluck announces that she will donate not less than $25,000 of the profits of her next season's concert tour to the Red Cross.

The Association of Military Dental Surgeons has sent out letters for the purpose of arousing interest in their work and increasing the membership of the organization. It is desired to have every dental surgeon and ex-dental surgeon of the army, navy, or National Guard become a member of this organization. The association now publishes a quarterly bulletin with dento-military news. At present it is contemplated to have at least 1,000 members in the Dental Reserve Corps. Dr. John D. Millikin is president of the association, which has its headquarters at 323 Geary Street, San Francisco, where applications for membership may be sent.

American Physicians to Aid French Civilians.—The American Red Cross is making arrangements to install an American physician in every village of appreciable size within the zone of the American army. The work is being done under the direction of American army surgeons. An effort will be made to better conditions among the French civil population and also to make certain that the American zone is in the best possible sanitary condition. In most instances Red Cross nurses will also be distributed among such villages. It has been found in many cases that the only doctors living in a town have been taken into the army, leaving the health of the community in the hands of old women.

Courts Bar "Golden Cross."—The "Golden Cross" organized to aid soldiers injured in the American army, navy, and aeronautical service has been refused a charter of incorporation by the Supreme Court on the ground that the proposed sphere of activities is properly and adequately covered by the Red Cross. A previous petition for incorporation was denied in July on the ground that the order proposed to maintain a hospital and give medical treatment and for this purpose approval of the State Board of Charities was required. The recent petition explained that this hospital was to be only a convalescent home for those discharged from medical treatment who needed rest and recreation. It is now stated that the new order proposes to devote its attention to the aeronautical branch of the service and that the plan has the sanction of various aeronautical associations.

Medical and Surgical History of the War.—Surgeon General Gorgas has established a board to collect material for the medical and surgical history of American participation in the European War. This board is composed of Col. C. C. McCulloch, librarian of the Army Medical Library; Major F. H. Garrison, assistant librarian in direct charge of work on the history, and Capt. John S. Fulton, secretary of the Maryland State Board of Health, who will have charge of the statistical work.

French Hospital of New York Honored.—Justin Godart, Under Secretary for the Army Medical Service of France, recently visited the place where the French Hospital of New York has conducted a military hospital of 250 beds since early in 1916, and bestowed medals of honor upon Dr. John Irwin and Dr. Thomas Savage who have served since the hospital started. Other medals were presented to a number of the nurses. M. Godart expressed regret that he was unable to bestow the decoration of the Legion of Honor on Major Culler, the head physician, until the consent of the United States Government could be obtained.

THE REHABILITATION OF THE CRIPPLED SOLDIER.

ONE of the most serious problems of the war in Europe has been how best to deal with disabled soldiers. The question was taken up first in Germany and France, but perhaps the most thorough methods of handling the matter have been devised in Canada. When an invalided soldier is brought back, his case must be completely and closely investigated and classified, in order that each case may be treated strictly on its merits. That such a scheme may be carried out properly, institutions of the nature of convalescent hospitals are required, for it is obviously impossible that an ordinary medical board could adequately fulfill this function; its members may not represent the various specialties, nor do they have time or opportunity for prolonged observation nor the equipment and facilities for undertaking such examinations. In Canada institutions of this kind have been and are being dotted about the country. A federal commission known as the Military Hospitals Commission was formed in Canada, the main object of which was to establish convalescent homes and training classes throughout the Dominion.

However, of our Allies France took the lead in designing schemes for rehabilitating the mutilés de la guerre and as Mr. Douglas C. McMurtrie has pointed out in No. 17 of the "Columbia War Papers," dealing with the war cripple, it was Edouard Herriot, mayor of Lyons, who undertook the organization in that city of a municipal training school for those incapacitated by war. In Great Britain, previous to this war, there existed the Incorporated Soldiers' and Sailors' Help Society, organized after the South African war to maintain workshops for disabled veterans, and this society has largely extended its activities. Up to a comparatively recent date, the British Central War Pensions Committee was responsible for the organization and management of the various measures initiated for the benefit of those disabled by war. Now the work has devolved upon the Ministry of Pensions. Italy and Russia also in the early months of the war inaugurated methods for caring for their cripples. In Great Britain the country has been divided up into areas for purposes of collective administration, and a scheme has been formulated for a Central Bureau for organizing the work of rehabilitation and reeducation of the discharged cripple.

The Paris Conference, according to an editorial in the *Lancet* of July 21, 1917, indicated definitely and authoritatively what the obligations of a country at war are toward its disabled soldiers. The recommendations made at this conference with regard to the restoration of function of such men may be summarized as follows: The earlier evacuation of the wounded man into an institute of physiotherapy; the provision of a sufficient number of well-equipped institutes with competent trained personnel; the attachment of an orthopedic surgeon to each field ambulance; the earliest possible application of medical gymnastics. The other resolutions dealt more particularly with the treatment of abiding disabilities by reeducation. A notable phase of this branch of the subject was that which suggested that a common policy towards the war cripple should be followed by the Allied nations.

But before going into the question of reeducation it may be as well to discuss briefly that of artificial limbs. Unless suitable artificial limbs are provided, it will be difficult, in many instances impossible, to reeducate or train vocationally the disabled soldier successfully. It must be decided among other things as to the type of limb to be used, the standardization of its parts, and whether in supplying limbs for the upper extremities the patient should be furnished with different kinds of limbs for different purposes, or with one limb with different attachments. So far as limbs for the lower extremities are concerned it is not so much ingenious ones which are required, but ones adapted to withstand the uses to which the lower extremities of a workingman are likely to be put.

Assuming then that the discharged cripple has been provided with appropriate substitutes for his lost limbs and, moreover, taught how to use them properly, he is, physically at least, in a position to receive vocational training and reeducation. In fact, it is high time that his social and economic rehabilitation should commence. In training a disabled man to be of use to his country and to preserve his independence and self-respect, his condition of mind and outlook on life must be taken into account. He is, generally, not only disabled in body, but sick in mind. His war experiences and the time spent in hospitals and in convalescent homes have tended to sap his energy and will power. Therefore, treatment must be adjusted to his condition. It must be impressed upon his mind that idleness will but accentuate the state of mind and body which his abnormal experiences have brought about, and that the best remedy is work. He must be shown that the loss of a leg or an arm is no insuperable obstacle to his future economic activity. The potentialities which exist in reeducation and vocational training must be made widely known to the disabled man. A move in this direction has been made in Great Britain recently by the

publication of a monthly journal entitled *Recalled to Life*. The avowed object of the journal is the diffusion of information among those concerned with the welfare of disabled soldiers and sailors, with regard to the means by which they may be restored.

In accordance with such views, and for the purpose of combating idleness and laxity in institutions established for training disabled soldiers, well termed curative workshops, these, as McMurtrie rightly insists, should be under military control. It goes without saying that the mind of the crippled man should be set at rest in regard to the care of those dependent upon him and his own future. When he is convinced that his family is provided for and that, by rendering himself an efficient worker he will not lose his pension, in the large majority of cases, with awakening health, he will have his initiative reawakened, his ambition stimulated, and he will quickly realize his responsibilities towards his country and himself. Furthermore, working in the company of numbers of other men, his spirit of emulation will be aroused, and the probability is that when he leaves the institution after undergoing a thorough training he will go out into the world an efficient workman who will be able to fight the battle of life almost as well equipped as his sound brother.

As noted in another column, Surgeon General Gorgas is alive to the necessity of reeducation of the crippled soldier and has already begun the organization of nineteen "reconstruction hospitals" of 500 to 1,000 beds each in the larger cities of the country.

THE VALUE OF THE X-RAY EXAMINATION IN CHOLELITHIASIS.

ROENTGENOLOGISTS, like specialists in some other lines, occasionally seem to be carried away by their enthusiasm and make categorical statements that are hardly warranted by the published experiences of other equally competent observers. The immediate occasion for this remark is furnished by the perusal of the initial sentence of James T. Case's article under the above caption in the *Annals of Surgery* for July, 1917, where he says: "One may be very sure of a clinical diagnosis of gallstones, but, as a matter of fact, he cannot be positive that gallstones are present unless he has seen them clearly in a roentgenogram." One may take issue with the writer of the above sentence for two reasons: First, because one often can be absolutely positive of the presence of gallstones from the clinical history and physical examination without radiography; and, second, because one cannot always be positive that gallstones are present when they are apparently shown on an x-ray plate. Practically all experienced surgeons have had many cases in which the positive preoperative diagnosis of gallstones could be and was made without resorting to radiography —this diagnosis being verified at operation; and these same surgeons have also been among the unfortunate victims of the radiographer's imaginative interpretation of shadows in the gall-bladder region, and have been much chagrined in cases of cholecystitis in not being able to deliver the expected souvenir of the operation in the shape of a bottle of gallstones, usually so highly prized by the patient for exhibition purposes.

Now, how much dependence can be placed upon radiography in the diagnosis of gallstones? Case states that from the radiographic standpoint cases of cholelithiasis fall under three heads: (1) Those where the gallstones consist entirely, or almost entirely, of pure cholesterin, and are therefore invisible to the Roentgen ray except in a few rare instances. (2) Those cases in which the large lime content of gallstones renders it almost impossible to overlook them, even during the most careless examination. Such stones, he says, can easily be made out fluoroscopically. (3) Those cases in which the lime content of the stone is relatively low and the stone can be made out only by means of the most careful technique. Taking the cases as they come the author concludes "that it is definitely possible to show gallstones in approximately 50 per cent. of the positive cases." He also states that Pfahler is convinced that gallstones can be found in about 50 per cent. of the cases. Case also credits Cole with finding gallstones in 20 out of 500 consecutive gastrointestinal examinations; but upon reading Cole's article, which was entitled: "The Roentgenographic Diagnosis of Gallstones and Cholecystitis," we find that, excluding all in which any doubt could be entertained, there was but five cases instead of twenty in which the preoperative radiographic diagnosis of gallstones could be considered as absolutely verified.

Turning to other sources of information, we find that George and Leonard seem to be the extremists in claiming value for the Roentgen diagnosis of gallstones, since they feel that 85 to 90 per cent. can be shown; while Caldwell seems to be perhaps the most conservative. The latter (*American Journal of Roentgenology*, 1915) says: "If we only make enough plates and make them well enough, we can obtain suspicious shadows in the gall-bladder region of any normal individual. The interpretation of gallstone plates, therefore, becomes a matter involving not only skill and judgment but temperament as well. In no other field of Roentgen diagnosis is the personal equation of the observer more important. This, I believe, is the best explanation of why some observers report as high as 85 per cent. and others as low as 5 per cent. of successes in these examinations." Carman, in his book entitled: "The Roentgen Diagnosis of Diseases of the Alimentary Canal," apparently leans more to the attitude of Caldwell than to that of the extremists; for he says: "Our (the Mayo Clinic's) own figures do not compare favorably with the larger percentages quoted above, notwithstanding the fact that abundant material has been at our disposal. Many of

the cases gave typical histories, but even in these, although extraordinary efforts were made, we have been able to obtain diagnostic shadows in only a small minority. The difficulty has been, not to find shadows, for these were often present, but to find shadows that seemed definite and characteristic."

Taking into consideration all of the above statements, it would appear that roentgenology has a definite corroborative value in the diagnosis of gall-bladder disease (cholecystitis, with or without gallstones) not only directly, by sometimes showing characteristic gallstone shadows, but also indirectly, as emphasized by Cole, through the demonstration of adhesions, etc.; but that so far as the positive detection of gallstones is concerned its value appears to be greatly overestimated by some authors. Even if a full clinical history is not furnished to the radiographer, the mere request for a study of the gall-bladder region implies the surgeon's suspicion at least of gall-bladder trouble; and the observer, perhaps subconsciously influenced thereby, is apt to report a hazy shadow as probably due to gallstones when he would not care to attempt a positive identification of the same shadow under other circumstances. The mere fact that so many guesses, hazarded under clinical conditions pointing perhaps almost indubitably to gall-bladder disease, are borne out at operation has undoubtedly led to an exaggerated conception, in some quarters at least, of the efficacy of the *x*-ray in the detection of gallstones. When the shadows are clear and characteristic the roentgen diagnosis of gallstones is generally reliable; but hazy, suspicious shadows should be considered only as a possible addition to the many bits of evidence which, taken together, point to the gall-bladder as the seat of a pathological process. We should also remember that cholecystitis is the disease and that gallstones are, as Carman says, incidental. This has been well shown at the Mayo Clinic, where 30 to 35 per cent. of the several thousands of diseased gall-bladders operated upon contained no stones.

Finally, since even the most radical admit the liability of error in the interpretation of shadows in the gall-bladder region, we would call attention to the suggestion recently made by several surgeons in this city to give a preoperative diagnosis of cholecystitis in frank gall-bladder cases, rarely making positive statements as to the finding of gallstones even in cases where the radiographer reports their presence. Under this plan it is explained to the patient that there is an inflammatory condition of the gall-bladder and that it is immaterial, so far as operative indications go, whether gallstones have yet been formed or not; hence there is less chance for dissatisfaction or distrust if, as is so often the case, stones are not found when a pathological gall-bladder is removed or drained. The wisdom of following this plan has been demonstrated so conclusively that it should be generally adopted.

THE DETECTION OF SEMEN.

Leaving out of the question the identification of bloodstains and the differentiation between human and animal blood, there is hardly a subject in the medicolegal branch of our profession which is so spectacular and upon which so much may hinge as upon the detection of semen. Cases of rape, criminal assault, seduction, and the like, present so many distressing features; and the punishment of a heinous crime or the delivery of an innocent person from a horrible accusation may rest so largely upon the testimony of the physician that the utmost care and technical knowledge are demanded before a positive opinion can be given. Then, too, the punishment, varying from the stern severity of the law to the atavistic violence of the mob, is so great for sexual crime, the history of medical jurisprudence is so replete with instances of plots against innocent persons, that the physician must be doubly careful in his examination.

The finding of semen in or about the sexual organs of the female in a case of alleged rape has a positive value, but its absence has no negative value. Neither *immissio penis* or *emissio seminis* are necessary to make a case of rape. However, the presence of semen in the vagina, about the vulva, or on the underclothing of the female, is presumptive evidence of a strong kind. The search should, moreover, be extended to articles in the immediate vicinity of the alleged assault—the bedclothing, the floor, ground, etc. If the victim of the assault be dead, the search should be extended into the uterus and tubes. There are a number of cases on record where motile spermatozoa have been found hours, days, and even weeks after coitus. They may even retain their vitality for several days after the death of the female.

In an article in the *Journal of Laboratory and Clinical Medicine* for December, 1916, Dr. Victor C. Vaughan has called attention to some features of this problem. Considerable stress has been laid, he says, in some quarters upon the contour, color, and odor of stains upon white cloth, it being held that these purely physical characteristics are enough to distinguish them as seminal stains. Vaughan deplores the tendency to jump at such a conclusion, especially in view of the great importance of the subject; the only evidence worthy of the name, he says, is the finding of spermatozoa. If these be not found the report must be negative.

The method he favors of examining such stains is briefly this: A part of the stain is rubbed up with physiological salt solution and allowed to stand a couple of hours. A milky fluid is thus formed, which can be examined directly under the microscope. If the stain be very old the salt solution should be rendered feebly alkaline with ammonia. A positive conclusion should not be based upon what appear to be the detached heads of spermatozoa, as granules of several sorts may be mistaken for these. Only complete cells, with head and tail, should be called spermatozoa.

Vaughan also describes other tests for semen and spermatozoa, notably the Florence method of preparing crystals from semen, but he believes that the only method which should be depended upon when the life or liberty of a human being is at stake is the actual detection of spermatozoa in the suspected fluid. This opinion will undoubtedly be concurred in by the profession. If expert medical testimony has fallen into some disrepute, one of the causes must be sought in the tendency to give a positive opinion on evidence of too tenuous a nature. Strict adherence to principles such as those laid down by Vaughan will protect us from many a pitfall.

Antiphones.

The literature of this subject is extremely small in proportion to its importance and the attempts that are constantly being made to obtund the hearing temporarily by mechanical devices. Instrument makers sell rubber antiphones which are relatively expensive and are not guaranteed to produce any definite results. Plastic substances, such as cotton tampons coated with vaseline, and plugs of chewing gum coated with lint to prevent adhesion are familarly known. People who employ these devices may complain that the desired effect is obtained only at the expense of disagreeable entotic noises. One of the recognized uses of antiphones is in patients about to go on the operating table, in the aim of diminishing peripheral irritation and of preventing the overhearing of chance remarks by the bystanders. In noisy neighborhoods and surroundings antiphones would be a boon to all who do mental labor. The war in Europe has made aural obtunders an absolute necessity, but the aim here is somewhat different, as the main desire is to prevent destructive changes in the ears when these are exposed to shell concussion, etc. In *La Presse Médicale* for August 6 we find a reference to a new type of antiphone which is extremely simple. It appears to be of the protective rather than the simple antiphone type—an empty gelatine capsule of the desired size which is warmed, oiled, and insinuated into the meatus. The complete cutting off of sounds is not desirable, for the soldier must be able to hear words of command, whistles, etc. A satisfactory antiphone for a student can only be secured through the compression of the protected ears by a spring. The external meatus should first be occluded with cotton, and a pad without should close the tragus. A C-shaped spring could be made to press firmly against the pads with the view of shutting out all sound for a relatively brief period. Such an "ear truss" may have been patented or extemporized in the past, but in the extant literature of the subject nothing of this kind is mentioned.

Abortive Cerebrospinal Meningitis.

While in theory there should be mild and abortive forms of this affection, cases in practice seem to be rare and dubious. We have silent cases, but these are none the less grave in type. A recently reported case of abortive meningitis is deemed worthy of an abstract in the *Journal de médecine et de chirurgie pratiques* for August 10. The case in question, reported by Rendu, was relatively silent. There was absence even of a meningeal reaction—no stiff neck, no lumbalgia, no Kernig sign, no fever. There were, in fact, but four symptoms, none of which was decisive, to wit, herpes facialis, slow pulse, brief headache, and vomiting. The former, which could have had no febrile causal factor in this case, is common enough in epidemic cerebrospinal meningitis. The slowing in the pulse is common in intracranial mischief. For the first night of the attack only there were headache and vomiting. The association of these four symptoms with lassitude comprised all the spontaneous objective phenomena. Spinal puncture was made and the pulse at once assumed its normal frequency. Although the abstract does not so state, we are led to believe that a positive diagnosis was made from the punctate. A puzzling feature in this case was the appearance of the meningitis soon after antityphoid inoculation. This might have been sufficient to cause the autoinfection of a simple carrier of the meningococcus.

News of the Week.

The Mayo Foundation Becomes Property of University of Minnesota.—The Board of Regents of the University of Minnesota has ratified by unanimous vote the permanent agreement making the Mayo Foundation at Rochester the absolute property of the University of Minnesota. The fund consists in securities totaling $1,650,345, which is to be used perpetually for higher medical education, research, and investigation. The expenses of the foundation will be paid by Dr. Charles H. and William J. Mayo until a fund of $2,000,000 has been accumulated. Thereafter the income from the fund will maintain it. The foundation has been affiliated with the university for two years as a trial. Under the final agreement the headquarters of the foundation can be moved from Rochester to any other point in the State after twenty-eight years. Ten per cent. of the yearly income will be expended outside of the State, and another 10 per cent. used to investigate epidemics inside and outside of the State. It has been announced that one of the Mayo brothers will go to France next year with the recruits and that they will take turns until the end of the war.

Hunger Increases Belgian Death Rate.—Recent reports from Belgium state that during the last four months the mortality in the industrial centers of Belgium and Northern France have increased from 15 to 65 per cent. per one thousand population. It is affirmed that this is largely the result of undernutrition. The Commission for Relief in Belgium has been unable to obtain ships to carry relief supplies, and cargoes of grain awaiting shipment in American ports have so deteriorated as to be unfit for food.

Infantile Paralysis Up-State.—Eleven cases diagnosed as infantile paralysis have been reported in Colton, St. Lawrence County. The schools are closed and children are barred from churches. There have been no deaths from the disease reported thus far.

Senior Military Medical Association.—This is the title of an association of Philadelphia medical

men who are beyond the age limit for admission to the Medical Reserve Corps, but who wish to serve their country in some way. The purpose is to band together men who are still capable of performing part time medical work, especially at or near the member's residence. "It is felt that members of the association can act as consultants in general and special physical conditions of recruits and conscripted men; also, in matters of sanitation and hygiene, and in making general physical examinations and mental and special examinations and in working in local hospitals or established places or cantonments where the sick or injured men may be sent; or those where fitness may be brought about in men medically rejected from admission to the service; also in performing any other work they may be capable of by the direction of the Government." The membership is not confined to Philadelphia residents, but includes physicians living in New Jersey, Pennsylvania, Delaware, and Maryland. The secretary is Dr. Alexis Dupont Smith, 5926 Greene Street, Germantown, Pa.

Contagious Disease Hospital for the Bronx.—Plans for a four story hospital for contagious diseases to be erected at Seton Avenue and East Two Hundred and Thirty-third Street, Bronx, have been filed. The new hospital will accommodate 1,000 patients. The building is to have glass partitions separating the wards and observation rooms.

Drug Sellers Sentenced.—The campaign against the traffic in habit-forming drugs was marked a few days since by the conviction of five offenders, three men and two boys. The three men were sentenced to prison for two years each and the boys were sent to the Elmira Reformatory for terms of thirteen and eighteen months.

Scarcity of Pure Zinc Oxide.—Examinations made by the Bureau of Chemistry of the United States Department of Agriculture show that there is very little zinc oxide on the market in the United States that complies with the standards of the U. S. Pharmacopeia. Nearly all the samples analyzed contained an excessive amount of lead. The samples were labeled "Not U. S. P.—Containing Small Quantities of Lead." This will be more likely to come to the attention of druggists than to that of physicians. The attention of physicians is therefore called to this fact so that they may protect themselves and their patients from possible injury when the pure article is required by calling for the U. S. P. article on their prescriptions.

Examination for Superintendent of Tuberculosis Hospital.—The Civil Service Commission of the State of New York announces that a competitive examination will be held on October 6, 1917, for the position of superintendent of the Iola Sanatorium for the Treatment of Tuberculosis, Monroe County. The position is open only to men, and carries a salary of $4,00 a year. Applicants must be graduates of an incorporated medical college, licensed physicians of New York State, and must have had at least five years in the actual practice of medicine. Applications must be filed with the Civil Service Commission, at Albany, not later than September 30, 1917.

Increase in Birth Registration Area.—The latest States to be admitted to the Registration Area for Births are Maryland, Virginia, and Kentucky. The Registration Area was established in 1915 and was then composed of ten States and the District of Columbia. It represented only 10 per cent. of the territorial extent of the United States, but contained 31 per cent. of the country's population. For this area the Bureau of Census has recently issued its first annual report. The war has brought a recognition of the need of complete birth registration as never before. The age of the soldier must be known. Since war was declared tests for the completeness of birth registration have been made by special agents of the Census Bureau in Virginia and Kentucky, and both States secured a rating of over 90 per cent., which represents the degree of completeness requisite for admission to the area.

Two Colleges Open Doors to Women.—Harvard University announces that it will hereafter admit women to the classes in its medical department. An announcement by Columbia University to the same effect was made some time ago.

The Association of Military Surgeons will hold its annual meeting at the Training Camp at Fort Benjamin Harrison, Indiana, October 8, 9, and 10. There will be much of interest to all physicians in the exhibition of the work of training going on in this camp, of the organization and field work of regimental detachments, ambulance companies, field hospitals, and evacuation hospitals. Those bringing their own blankets and cots or mattresses can be accommodated in camp at a cost of $1 per day.

The American Public Health Association will hold its annual meeting in Washington on October 17-20. The discussions will deal largely with problems of sanitation in relation to war.

Obituary Notes. — Dr. WILLIAM AUGUSTUS SCHNECKER, a graduate of the College of Physicians and Surgeons, in 1899, died at his home in New York City, on September 13, aged 40 years.

Dr. ABNER J. P. JULIAN, a graduate of the University of Maryland School of Medicine, in 1883, and a practitioner of Lake City, Fla., died August 25, aged 58 years.

Dr. ZACHARIAH TAYLOR MARTIN, a graduate of the Cincinnati College of Medicine and Surgery, in 1881, formerly superintendent of the Missouri Hospital for the Insane, and more recently a member of the staff of the Pettey-Wallace Sanitarium, Memphis, Tenn., died suddenly of asthma, on August 26, aged 70 years.

Dr. DAVID ST. JOHN, a graduate of Bellevue Hospital Medical College, in 1875, a practising physician of Hackensack, N. J., died at Berne, N. Y., August 14, aged 67 years.

Dr. JOHN L. OVERHOLT, a graduate of the Charity Hospital Medical College, New Orleans, in 1887, died suddenly of heart disease in his office at Columbus Junction, Ia., on September 1, aged 50 years.

Dr. FRANK CORNWALL, a graduate of the Eclectic Medical College, Cincinnati, Ohio, in 1869, died at his home in San Francisco, August 31, aged 71 years.

Dr. CHARLES G. PRATT, a graduate of the University of Michigan, in 1901, died of Bright's disease at his home in Sparta, Mich., August 31, aged 41 years.

Dr. WILLIAM P. BOUTON, a graduate of the Louisville School of Medicine, died at Lebanon, Tenn., September 3, aged 69 years.

Obituary.

LEWIS ATTERBURY STIMSON, M.D., LL.D., F.A.C.S.

NEW YORK

Dr. Lewis A. Stimson died suddenly at his summer home in Shinnecock Hills, L. I., on Monday of this week. He was born at Paterson, N. J., in August, 1844. He was graduated from Yale College in 1863, and immediately entered the Union Army, in which he served as captain until the end of the Civil War. After a period of European travel and study he returned to this country and entered the Bellevue Hospital Medical College, from which he was graduated M.D. in 1874. He was professor of physiology, 1883-5, of anatomy, 1885-9, and of surgery, 1889-98, in the New York University Medical College, and in 1898 was called to the chair of surgery in the Cornell Medical College in New York City. He was one of the regents of the University of the State of New York from 1893 to 1904. He was consulting surgeon to the New York and Bellevue Hospitals. Dr. Stimson was the author of a work on "Operative Surgery," published in 1900, and of the well-known and popular "Treatise on Fractures and Dislocations," the eighth edition of which was published this year, and had also contributed largely to general literature. He was an enthusiastic yachtsman, and not many years ago sailed his own boat in a race across the Atlantic. He was a member of the American Surgical Association, the New York Academy of Medicine, and the Medical Societies of the State and County of New York.

Correspondence.

"RESEARCH WORK INTERRUPTED."

To the Editor of the Medical Record:

Sir:—The impression which the letter with the above caption from Dr. Paul Luttinger, published in the September 8th issue of the Medical Record, is designed to give, and certainly would give to the readers, is that his dismissal from the Department of Health was due to opinions expressed by him as to the effects of alcohol, following his studies carried on in the Research Laboratory, under the auspices of Dr. William H. Park.

Dr. Luttinger was dismissed from the Department of Health after a hearing before the Board of Promotions, consisting of the Directors of the Departmental Bureaus, who recommended his dismissal because of insubordination and disobedience to direct orders issued to him. This insubordination and disobedience had no relation whatsoever either in time or in matter with the studies on alcohol which Dr. Luttinger had at a previous date made and reported upon to Dr. Park. The Board of Health passed upon the charges against Dr. Luttinger, and agreed unanimously that Dr. Luttinger's behavior to the assistant and acting directors of the Bureau of Laboratories, and his insolent disregard of orders given to him, merited his immediate dismissal from the department, and they so voted.

Some months ago, Dr. Luttinger was assigned by Dr. Park, at my request, to review the literature and make original experiments to control, verify, or controvert the published reports as to the effect of alcohol in modifying the resistance of warm blooded animals to infection. Dr. Luttinger was allowed the same freedom and facilities in carrying on his research that is allowed to all research workers in our laboratories. His preliminary report, as presented, was so superficial and incomplete that Dr. Park and I thought further studies should be made before presenting any statement in published form.

For the credit of the Research Laboratory of the Department of Health of this city, and to correct the impression which Dr. Luttinger's letter could not fail to create if unanswered, I request the publication of this letter in the next issue of the Medical Record.

H. Emerson, M.D.,
Commissioner.

Department of Health,
City of New York.

6. Further Observations on Shock at the Front. W. T. Porter.

4. Bruck's Sero-Chemical Test for Syphilis: A Report of 400 Cases Compared with the Wassermann.—Curtis E. Smith and H. C. Solomon say that they commenced these experiments with a great deal of skepticism and were very much surprised at the results obtained, and that whatever the final status of the test a great deal of interest attached to the fact that this simple chemical reaction does pick out certain differences in the blood sera, and that apparently a large number of syphilitic sera differ in their percentage composition from the majority of non-syphilitic sera. The writers describe the modifications of Bruck's technique which they have found most satisfactory, and which eliminate certain errors likely to occur in the original method. In 101 of these 405 cases there were definite clinical manifestations of syphilis, in which the Wassermann and Bruck tests agreed positively in 74 or 75 per cent. The two tests agreed negatively in twelve instances, and were at variance in fifteen. In the group which showed syphilis of the nervous system they had sixty-four cases of clinically certain general paresis, of which the Wassermann and Bruck tests agreed in fifty-four instances, or practically 85 per cent. In other forms of central nervous system involvement the agreement was 100 per cent. in the fifteen cases tested. In the cases with no apparent involvement of the nervous system the agreement was somewhat less, being 76 per cent. This may be in keeping with the fact that the Wassermann test was not so strongly positive in these cases. The advantages of the test are: (1) the short time required to do the test, (2) the limited amount of apparatus necessary, and (3) the simplicity of the technique. The disadvantages of the test seem, for the most part, to be bound up in the personal variations that are apt to occur. We are here dealing, most probably, with a quantitative chemical difference in the protein content of syphilitic and non-syphilitic sera, the nature of which is not understood by us. It is our hope that this may be brought to light in the near future in the field of chemistry.

6. Further Observations on Shock at the Front.—W. T. Porter has in previous communications described his investigations which showed that blood pressure of soldiers on active duty in the trenches was not increased and that it was not lowered under habitual bombardment. In a second communication the writer recorded

the discovery that shock is caused by fat embolism, and he later showed that the low blood pressures of shock were raised 15, 20, and even 30 mm. of mercury by increasing the aspiration of the thorax. From further investigations it now appears that increased respiration from the administration of carbon dioxide is of advantage in shock. In his experience it has not failed to raise blood pressure even in profound shock. In his observations made at Vautin the head of the wounded man was placed in a wooden box, the length, breadth, and height of which were approximately 33 cm. The end for the neck was in two pieces, in which the neck fitted as in a guillotine. Cotton was placed between the edges of the openings and the skin. A hole about 2 cm. in diameter was made in each of the two sides of the box. Cotton was placed in these holes to regulate the amount of carbon dioxide and air. The carbon dioxide entered the box by one of these holes. Enough gas was used to double the respiration. The writer believes it would be of advantage to use carbon dioxide during operations. Great care should be taken to discontinue the carbon dioxide respiration very gradually.

8. A New Group of Symptoms in Terminal Gastric Catarrh. Roy Upham.

1. The Treatment of Paresis.—Britton D. Evans and Frederick H. Thorne have, during the past two and one-half years, treated twenty-three patients intraspinously with salvarsan, neosalvarsan, and albuminate of mercury. Fifteen of these cases were reported one year ago but at that time sufficient time had not elapsed to permit of a definite conclusion in regard to the therapeutic value of these agents. The smallest number of injections given to one patient was three and the largest number was twenty. The Wassermann reaction was temporarily reduced to negative with the blood serum of one patient and the cerebrospinal fluid of three. Three patients showed some mental and physical improvement; ten died, four during the course of treatment, and six several months after the treatments were discontinued. Ten are living and are markedly demented. From the results in this series of cases it would seem that the intraspinous method of treating paretic dementia has little or no therapeutic value. As a rule considerably more reaction was observed following the treatments with mercurialized serum than with the salvarsanized serum.

2. The Imperfect Sight of the Normal Eye.—William H. Bates states that after thirty years of study of the refraction of the eye under different conditions he is convinced that the normal eye, contrary to the general belief, has imperfect sight most of the time. Of 20,000 school children studied by him more than one-half had normal eyes with perfect sight. Not one of them had perfect sight in each eye every day. The sight of many of them might be good in the morning and imperfect in the afternoon, while many with imperfect sight in the morning would have perfect sight in the afternoon. The amount and degree of imperfect sight varied within wide limits from one-third of the normal to one-tenth or less. The duration of the imperfect sight of the normal eye was also variable. Under some conditions the imperfect sight in the classroom might continue only a few minutes or less; under other conditions the imperfect sight might last for days or weeks or longer. There is but one cause of functional imperfect sight and that is strain or effort to see. Strong light and noise are frequently causes of defective vision of the normal eye. Eye training with the aid of the Snellen card at ten feet or farther is very successful in correcting and in preventing the imperfect sight of the normal eye. With training the vision always improves and becomes better than that of the average normal eye. On the author's recommendation more than 20,000 school children have practised eye training daily with the aid of the Snellen test card. The results were of great practical importance. The vision was always improved when the teachers used the method properly. Because the sight was always improved myopia was prevented. Many children wearing glasses to benefit imperfect sight, pain and fatigue of the eyes, and headaches were relieved so completely that they were able to discard their glasses and obtained more perfect sight and a greater relief than the glasses had afforded. Artists, bookkeepers, lawyers, physicians, writers, mechanics, and others found their efficiency increase many times with the aid of eye training. The good results obtained justify the use of the method in all schools, the army, the navy, the merchant marine, on the railroads, and in short by every body who desires or needs continuous perfect sight.

1. The Nonspecific Character of Vaccine Therapy.—Joseph Miller reviews certain experimental work which goes to show that the results obtained from the use of vaccines have been due not to the specific character of the vaccines, but to the foreign protein. He describes his observations with reference to the application of foreign protein therapy to the acute, subacute, and chronic arthritides, and states that during the last year and a half they have treated 175 cases at the Cook County Hospital, including streptococcus and Neisserian types. They have used the typhoid vaccine almost exclusively as foreign protein, and in a few cases proteose and chicken serum; the latter were used in a sufficient number of cases to show that the results were apparently the same as with the typhoid vaccine. In a series of ninety-three cases of acute arthritides, in which quite complete records were kept, eighty were greatly benefited or relieved of their pain and soreness by one to four injections given daily. Six showed only moderate improvement, and seven were not benefited, although receiving repeated treatments. Thirty-three of the acute arthritides patients had been under active salicylate treatment before receiving the foreign proteins without benefit. All but four of these were promptly relieved, at least temporarily by the typhoid vaccine. Eighteen patients with subacute arthritis received the treatment. Fourteen of these were definitely benefited. Recurrences here were common, but in conjunction with the protein an effort was made to clear up any foci of infection. Twenty-eight patients with chronic arthritis received the treatment. In these definite temporary improvement was quite frequently observed. The results

of the whole series were sufficiently suggestive to warrant the continuance of the treatment in selected cases. The chief difficulty in this form was therapy in the violent reaction. It has been the writer's experience that when the injection was not followed by a chill, although there might be a marked leucocytosis, no definite beneficial results have been obtained.

7. Value of Blood Pressure Determinations in the Practice of Obstetrics.—J. Morris Slemmons. (See MEDICAL RECORD, June 9, 1917, p. 1016.)

8. Diverticulitis of the Large Intestine.—William J. Mayo. (See MEDICAL RECORD, June 16, 1917, p. 1063.)

11. Report of an Outbreak of Diphtheritic Wound Infection Among Returned Soldiers.—J. G. Fitzgerald and D. E. Robertson, who are in charge of the Military Hospital in Toronto, state that, having found several cases of wound infection which revealed the presence of *B. diphtheriæ*, they commenced a thorough investigation of all infected wounds, stumps or other, in returned men of the Canadian Expeditionary Force who were in the hospital or were out-patients of any of the military convalescent hospitals. Between May 20 and June 7, 1917, sixty-seven men with suppurating wounds, chiefly amputation wounds, were swabbed. Of this number, thirty-two were found to be suffering with *B. diphtheriæ* infection. The source of the infection could not be definitely traced, though it seemed that at least a part of it had come from overseas. However, the possibility of such an infection being spread by a carrier is suggested. Of the men with wounds infected with the *B. diphtheriæ*, six at least had what looked like diphtheritic membranes, and clinically they somewhat suggested diphtheria because of toxic symptoms, but there was not a single instance of infection of the mouth, nose, or throat. The wounds in which the infection was due to the *B. diphtheriæ* invariably began to clear up when antitoxin was administered. Such cases showed no improvement when treated with acid solution of hypochlorite.

14. Pulmonary Edema in Pneumonia and Its Treatment.—W. A. Bastedo, after discussing the etiology of pulmonary edema, states that our therapeutic aim must be to lessen the production and increase the removal of fluid. Both objects are to be accomplished by improvement of the pulmonary circulation and by attention to the contributory factors. In all cases, therefore, cardiac failure is to be treated. In addition, therapeutic consideration may be required for respiratory insufficiency, acidosis, deficient oxidation, and abdominal distention. The treatment of cardiac failure is by digitalis, not by nitroglycerin. Venesection is one of the most reliable procedures in the pulmonary edema of pneumonia, as it not only has the effect of lessening venous congestion, but by lessening the alkalinity of the blood will counteract a tendency to acidosis. To stimulate the respiratory insufficiency the writer finds that the three drugs of most value are atropine, caffeine, and strychnine. Further treatment for respiratory insufficiency may be oxygen inhalations, artificial respiration, the removal of mechanical impediments to breathing, and counterirritation. Lowering the head-end of the bed has been practised with benefit in edema of the lungs from pilocarpine and anesthetics. It is possible that some change of posture in pneumonia may favor the emptying of the lungs. The administration of sodium bicarbonate to counteract acidosis should not be given either by rectum or intravenously, but by the mouth. If giving it by the mouth is not feasible, it may be given intravenously in hypertonic 10 per cent. solution in amounts of 400 c.c. In the writer's experience this has been well borne.

The Lancet.

2. Horseshoe Kidney by Union of the Upper Poles, Diagnosed Prior to Operation. With Calculus in Lower Pole on Left Side. David Newman.
3. A Case of Claustraphobia. W. H. R. Rivers.
4. Perforations of the Stomach and Duodenum. James Taylor.
5. The Problem of Tuberculosis. H. Hyslop Thomson.

1. The Immediate Effect of Smoking on Healthy Men and on Cases of "Soldier's Heart".—John Parkinson and Hilmar Koefod say that in this war, as in wars of the past, many soldiers prove inefficient because they become unduly breathless on the exertion that military service entails. The same individuals often complain of precordial pain, palpitation, giddiness, and exhaustion. Some of these cases present the signs of valvular disease of the heart and are discharged from the army, yet in the majority of soldiers in whom these symptoms are found no abnormal physical signs are found. To find out whether excessive cigarette smoking is one of the potent causes of this condition they have made observations in which attention was directed to the effect of smoking on the (1) pulse, respiration, and blood pressure, and on (2) reaction to exertion. Thirty smokers were observed, of whom twenty were cases of soldier's heart, and ten were healthy soldiers. Each subject smoked either four or five cigarettes during a period of forty minutes. A demonstrable effect was recorded in seventeen of the twenty subjects; the three unaffected were non-inhalers. Nine of the ten controls, all inhalers, were influenced in the same fashion, though not to the same degree. The average pulse rate among the patients during the smoking was nine beats higher than before smoking; in the healthy controls it was six higher. Initial slowing of the heart was never observed, nor any irregularity referrable to smoking. The rate of inspiration in the patients was unaffected; in the controls it was slightly reduced. The average systolic blood pressure was raised by 5 to 10 mm. of mercury and the systolic by 5 mm., both in patients and controls. These effects appeared within five minutes; with the first cigarette they almost reached the maximum, and this was maintained throughout the smoking period. A simple exertion test was performed before smoking and repeated on its cessation. In the patients the pulse rate maintained a higher level throughout the test after smoking, and half of them were more breathless, both subjectively and objectively. In two patients precordial pain was induced by smoking, apart from the exertion. But in the controls the pulse rate curve during exertion was much the same after smoking as before, and breathlessness was induced in two only. These observations show that in health the smoking of a single cigarette by an habitual smoker usually raises the pulse rate and blood pressure perceptibly; and these effects are a little more pronounced in cases of "soldier's heart". Moreover, the smoking of a few cigarettes can render healthy men more breathless on exertion, and manifestly does so in a large proportion of these cases. Excessive cigarette smoking is not the essential cause in most cases of soldier's heart; but in the opinion of the writers it is an important contributory factor in the breathlessness and precordial pain of many of them.

4. Perforations of the Stomach and Duodenum.—James Taylor relates his experience with perforations of the stomach and duodenum in the central surgical military hospital of a large camp. The type of ulcer met with was usually the chronic variety with a great deal of induration around, and there was usually a definite history of gastric trouble over a long period. The condition in which one got these cases differed very little from that of civil practice. A collection of cases operated on by Mayo, Robson, Finney, Moynihan and Christy Wilson shows the following results: Total number, 486; recovered, 227; died, 259; percentage recoveries, 44.6. The results of the Edinburgh Surgeons, Caird, Stiles, Miles, and several others between 1910 and 1913 were as follows: Total number of cases, 80; total recoveries, 53; number of fatal cases, 27. Percentage death rate, 34.2. The writer had twenty cases, and of these five died, a death rate of 25 per cent. Rather more than one-half the cases were perforations of the stomach, and there were four deaths in the gastric series against one in the duodenal. The writer discusses the difference of opinion with reference to the advisibility of a primary gastroenterostomy. In his series primary gastroenterostomy was done in six of the cases. These were all recoveries, and they ran altogether a happier course than the ones in which it was not done. It might be said that the operation was done in the cases that were not very ill and in which the prognosis was more favorable in any case. In this series this was usually so, but not always. In cases of ulcer on the lesser curvature or anywhere away from the pylorus suture cannot give rise to additional trouble,

and as improvement after gastroenterostomy is only expected in one-third of the cases of simple ulceration it does not seem advisable in cases that have perforated to prolong the operation for such a doubtful chance of improvement. The case in this series operated on longest after perforation was over forty-eight hours, that with recovery twenty-seven hours. While the life of most of these patients was saved, and most of them would be quite useful citizens afterward, few of them would be of much use to the army, although many, in fact most of them, returned to duty. Itis difficult to make these men fit to take the army diet. Among cases operated on for simple gastric or duodenal ulcer, and though they were greatly improved and seemed perfectly well while in the auxiliary hospitals, they relapsed a short time after their return to duty and the ordinary fare. On the other hand, officers, who have had a certain choice of food, have made perfect recoveries after operation, and have been able to return to full duty in a comparatively short time.

3. Acetozone as a General Surgical Antiseptic.—G. Gore-Gillon and R. T. Hewlett have used benzoyl-acetyl-peroxide extensively in military hospitals since May, 1915, and find that it fulfills the conditions requisite for an ideal antiseptic; namely, great potency against all microorganisms, no deleterious effect on phagocytosis, is innocuous to the tissues, and has a stimulating effect on connective tissue cells. Its action is very rapid; unhealed amputation stumps heal very rapidly if put in a bath of this solution for half an hour daily, and dressed afterward with dressings of sterile lint or gauze soaked in the 10-grain solution; septic wounds which have resisted all other treatment for four or five months have healed up in three weeks by this method. The solution must be made by adding 5 to 7 grains to 1 pint sterile water at 112° F., left to stand for two hours, and should not be filtered. Or a 10-grain to 1 pint solution can be used with dressings or Carrel-Dakin tubes, etc. In very septic cases, swarming with anaërobes, etc., a 20-grain to 60-grain solution may be used. It should be made fresh every seven days, and the bottle shaken before using. Used in a 20-grain solution it is an efficient sterilizer of the skin. Professor Hewlett has made tests of the germicidal power of acetozone. His results show that it is a potent disinfectant. In saline mixtures it kills the staphylococcus in strengths of 1/600 in thirty minutes and in 1/24,000 in twenty-four hours. The addition of serum and broth reduce its germicidal power, but it is still effective in strengths of 1 in 437 and 1 in 1,744, respectively, with an exposure of twenty-four hours. With sporing mycoides in saline mixture it kills in strengths of 1 to 437 in one hour and 1 in 1,744 in twenty-four hours. With a mixed culture of sporing anaërobic bacilli grown from a septic wound, 1 in 290 killed in twenty-four hours. One in 290 is equivalent to 30 grains to the pint; 1 in 437 is equivalent to 20 grains to the pint, approximately.

6. A Case of "Spontaneous" Rupture of the Spleen: Splenectomy: Recovery.—W. Rankin reports this case both on account of the rarity of rupture of the spleen as an abdominal catastrophe in this part of the world, and so that medical officers may be reminded of the necessity of examining the spleen in patients that have served for a period abroad. The patient was admitted to the hospital with symptoms of an acute abdominal condition requiring immediate operation. At operation a very large spleen was removed, the capsule of which was torn and the surface covered with a firm clot. The bleeding had been very profuse. The parasite of malaria was present in great numbers. No crescents were found, and while the case looked like a malignant one, the opinion expressed was that the patient had a double infection of the tertian type. This patient had served in India, where he had attacks of malaria, but was never in the hospital and no blood examination was made. Later, while at Salonika, he had an attack of malaria and was in the hospital for five days, and attended for three weeks, taking quinine. He then had an operation for appendicitis and was invalided home. After recovering he noticed that any heavy work or activity gave him a feeling of discomfort in the stomach and after much exercise he vomited on several occasions. He had been uncomfortable for five days before the rutpure occurred, but had suffered no special trauma. The spleen after removal was about eight times the size of the normal organ and must have been much larger before it ruptured. The patient made a very good recovery.

Left and Right Diastolic Murmurs in Aortic Insufficiency.—Trémolières, Caussade and Toupet refer to the classic teaching that for aortic sounds one listens at the inner angle of the second right costal interspace. Here one may overhear the soft and double diastolic murmurs which indicate respectively the existence of Corrigan's disease and Hodgson's disease. A few specialists have insisted that these murmurs are best heard to the left of the sternum, along its border and toward the ensiform cartilage. The authors have of late examined many soldiers with cardiopathies and are inclined to assent in part to the minority report as above stated, *i.e.* they found that for at least the first half of the adult period of life the left side of the sternum is a more dependable region for auscultation. Of 60 cases studied but 10 gave the best results at the classical site, while in 26 to the left of the sternum was the preferred location. But in 20 cases the murmurs were best heard directly over the sternum and in 9 others over the ensiform cartilage. It is evident that the results of auscultation must be backed up with other evidences which are readily forthcoming. Again the site of the murmur may give way in importance in part to the pitch and direction of propagation. The entire group of peripheral signs of aortic insufficiency is available, and the *x*-ray in these cases may give all the certainty of an autopsy find and besides almost does away with the need of auscultation and percussion, showing as it does the exact amount and kind of deformity of the heart. The authors attempt to account for the auscultatory confusion in these cases of aortic insufficiency. Much depends upon the lesion whether this is a pure hypertrophy of the left ventricle or a hypertrophy associated with dilatation. Upon the screen two very different heart shadows appear, and it is readily experienced that in the advanced case with dilatation the aortic sounds are heard most distinctly in the old classical location, *i.e.* to the right of the sternum and high up. Conversely in the recent lesion of the aorta in which there is simple hypertrophy of the left ventricle the aortic sounds are heard most clearly to the left of the sternum. This appears to the authors to be a very simple solution of a very complex problem. The old classical teaching was not wrong but simply incomplete. The period of incipient disease of the aorta coincides with the first half of adult life (military age), while the diseases understood in the classical teaching were doubtless advanced stages of the same type and hence more manifest at a more advanced period of life.

Problems of Metabolism and Immunity in Dermatology.—Bloch refers to the return of the conception of diathesis in dermatology. Today it means a particular type of reaction toward certain insults. Many dermatoses occur by preference in those with the socalled exudative diathesis, but the latter has many clinical expressions and we wish something more tangible. Hence we may contrast with the more or less empirical exudative diathesis and its cutaneous expressions the correlation

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 27, 1917.

DR. GEORGE W. KOSMAK IN THE CHAIR.

Instrument for Making Internal Pelvic Measurements through the Rectum.—Dr. T. H. CHERRY made this presentation. He stated that there were many reasons why rectal examination should be employed during pregnancy. Chief among these was the fact that the genital canal was not contaminated by the examining fingers of the accoucheur. The simplicity of the examination and the fact that no sterilization of the genitals was necessary were also factors in favor of this method of examination. Furthermore, the hands of the obstetrician could be saved a considerable amount of trauma by the fact that it was not necessary for him to scrub his hands. Any number of examinations could be made on the patient with impunity without fear of contamination. In cases that were seen for the first time after labor had set in, the writer had been impressed with the fact that it was not an easy matter to ascertain that the pelvis was contracted or normal by the use of the rectal examination alone. He had, therefore, attempted to devise an instrument by which the internal pelvic measurements could be estimated through the rectum. It had been the writer's observation that, when making a rectal examination, if the promontory of the sacrum was reached with difficulty or not palpated, the internal conjugate was in all probability of sufficient length for the passage of an average sized fetus. The instrument which he had devised consisted of a straight bar, 13 cm. in length, with a rounded tip and graduated in centimeters. An upright bar, 4½ cm. in length, met the first bar at right angles and was attached to it by a sliding device that permitted it to be arrested at any point on the first bar and it could there be made fast by a set screw. The first long bar was inserted into the rectum alongside the index finger and placed on the promontory of the sacrum. The sliding bar was then moved so the tip could be easily placed under the symphysis pubis and when this was accomplished the screw was set and the distance could be read on the scale. This distance was the diagonal conjugate and was readily ascertained by measuring the distance between the tips of the upright and horizontal bars with an ordinary pelvimeter. From the diagonal conjugate it was easy to estimate the true conjugate by subtracting 1½ or 2 cm. To facilitate obtaining the diagonal conjugate there had already been measured on the upper surface of the horizontal bar the hypotenuse of each triangle at each centimeter mark, so that all that was necessary after the two fixed points of the promontory and symphysis had been obtained was to read the result upon the scale.

Hemorrhagic Abdominal Sinus.—Dr. JOHN W. WARREN reported this case. He stated that the patient, a woman twenty years of age, had been married sixteen months, during which time no pregnancies had occurred. Menstruation had been normal and the patient had always been perfectly normal until six months previously, when she developed severe abdominal pain, with fever, chills and vomiting. A left salpingo-oorphorectomy, a right partial salpingectomy, and some form of ventral suspension was performed. Both tubes contained pus. About 3 cm. of the right tube was left in order to give the patient a chance for subsequent pregnancy. The wound was drained by rubber tubes and packing for about six weeks, and more effective drainage was finally obtained by colotomy. During the patient's stay in the hospital blood was observed on the dressings at the time of menstruation. The patient was discharged with a small sinus on the right side about 4 cm. from the midline. At each menstruation following there was a moderate discharge of blood from this sinus. The uterus was found very free and movable in view of the extensive inflammatory process of recent date. The left fornix was free except for some resistance, and on the right side the ovary could be palpated. A small quantity of argyrol injected into the sinus soon appeared at the external os. A sound in the uterus and a probe in the sinus could be approximated, but no metallic click was obtained. Diagnosis was made of sinus leading into the uterine cavity. An operation was performed which consisted in dissecting out the sinus tract. It was found that the sinus tract was largely composed of the stump of the tube, and communicated directly with the cavity of the uterus. The remains of the tube, with its insertion into the corpus, was excised, and the sinus closed in a few days. A search of the literature failed to show a duplicate case. It was manifestly fair and right to leave a portion of healthy tube when possible and thereby to assure the patient that she had at least a chance of becoming pregnant, but where one unfortunately came upon acutely infected tubes, distended with pus, if they were to be removed at all, it would seem wiser to completely excise them together with a wedge from the horn of the uterus.

Dr. MEYER RABINOWITZ said that if the discharge from the abdominal sinus was bloody and its occurrence was simultaneous with the menstrual period, then one ought to conclude that there was a reverse flow from the uterus into this sinus, which at operation proved to be the proximal portion of the Fallopian tube. An occurrence of this nature was contrary to physiological laws and this case ought rather to be regarded as one of those anomalous conditions in which a bloody transudation did take place in the Fallopian tube during menstruation.

Dr. MICHELE CATURANI stated that he had had two cases in which bleeding through a sinus had occurred at the time of menstruation. He thought the bleeding might be due to general pelvic congestion occurring at this particular time.

Dr. WARNER, in closing, said that what he regarded as of prime importance in this case was that though one preferred to leave a piece of the tube where it was safe to do so, it had been a mistake to do so in the present instance. Where the blood came from he could not say.

Abdominal Pregnancy: Removal of the Sac: One Year after Spurious Labor.—Dr. MICHELE CATURANI reported this case. The patient was thirty-three years old. Menstruation began at the age of thirteen years and had been regular in type. She had been married thirteen years and her last child was eight years old. She had her last menstrual period Sept. 9, 1913. She never had any irregular bleeding, and never suffered any considerable pain. Her pregnancy appeared to be a normal one until July 2, 1914, when she was seized with abdominal pain and labor was supposed to have set in. The pains lasted four days and were accompanied by severe vomiting and fainting spells. With the appearance of genital bleeding the pains subsided. The menstrual periods returned with regularity and nothing worried the patient except the persistent and gradually diminishing enlargement of the abdomen. In July, 1915, she missed the menstrual period and consulted Dr. Caturani, who found a large cystic, tense mass on the left side of the pelvis and abdomen, well above the umbilicus, and closely connected with the uterus, but entirely distinct from it. The uterus showed early signs of pregnancy. He did not pay much attention to the previous history and did not recognize the real nature of the condition, and both before and during the operation he was more inclined to believe that he was dealing with a dermoid cyst. The operation performed on July 12, 1915, was a simple one. The cystic sac and left adnexa were removed. Upon opening the sac the true condition was revealed. A pint or more of dense, dark-colored fluid came out, and in the cavity appeared the remnants of a completely macerated fetus. The uterine pregnancy present at this time went undisturbed to term.

Pseudohermaphroditism: Testicle in Woman.—Dr. MICHELE CATURANI reported this case. This rather rare case was in an Italian, twenty-six years old, who had never menstruated. Since she was very young she had noticed the intermittent appearance of a swelling in the left inguinal region. At the time she presented herself to him she had been married six years and had never encountered any difficulties in sexual relations. Local examination showed the external genitals evidently feminine, but of pubescent type. The vagina ended in a cul-de-sac, in the center of which

the examining finger detected a slight projection (cervix) and a body not much greater in size than the cervix. There was no trace of ovaries on the left side. Deep palpation on the right side brought out a body the size of a large almond, which seemed to be situated high up in the pelvis, almost in the iliac fossa. In the left inguinal region the canal admitted the finger and under the slightest strain the patient forced out a mass which distinctly contained a solid round body. The general examination showed the woman to be feminine in type. The mental development was about normal. She displayed considerable astuteness. She had been continuously deceiving her husband and her sister simulating the normal occurrence of the menstrual periods and giving credit to the occurrence of several miscarriages. The patient reported the sexual impulse absent, though she passively submitted to coitus. Feminine pudor was apparently absent, judging from the way in which she submitted to photography. Operation was performed on June 24, 1914, with the purpose of repairing a hernia on the left side, reconstructing the weak inguinal canal, and ascertaining the conditions of the pelvic structures. Outside of the rudimentary body of the uterus and two folds stretching out from it, there was no trace of uterine appendages in the pelvis. High up in the pelvis, toward the sacroiliac synchrondrosis there was an ovoid body similar to the one removed with the hernial sac of the left side and which proved to be a testicle. The area of testicular tissue was 3.5 x 2 x 1.5 cm. It was enclosed in a firm, thick tunica albuginea. On section the tissue had the usual appearance of a gland testis with an unusual brownish tinge. The tissue was composed of irregular lobules of characteristic testicular tubules lined by three or four rows of well nourished cells, sometimes enclosing a lumen. There were no signs of spermatogenesis. No structures of rete or epidydymis were found.

Dr. THOMPSON T. SWEENEY said he would like to hear some embryologist explain the feminine development in Dr. Caturani's second case. The woman had only a bud of a uterus and the ovaries were absent. Under these conditions one would have expected her to tend toward the masculine type of body. Dr. Sweeney cited an instance of an individual coming under his observation at the Post-Graduate. They thought they were dealing with a simple case of hypospadias, but this person had a pouch for a vagina, an inch or an inch and a quarter in depth, and undescended testicles. She had a rudimentary penis and they advised operation on this, since she was engaged to be married, and to have told her that she was a male would have necessitated the reorganization of her entire life.

Dr. S. WIENER said that he had operated on a case in some respects more remarkable than either of the two cited. This patient, eighteen years of age, had presented herself to him because she had never menstruated and there was a swelling in both inguinal regions. The breasts were of well developed feminine type. The development of the external genitals was about that of a twelve-year-old girl. The vagina was about two inches in depth and presented a normal appearance, except for the absence of rugæ. A small solid body, like a rudimentary uterus, could be palpated in the vault of the vagina. In each inguinal region there was a round ovoid body. This, Dr. Wiener said, he took to be a double inguinal hernia of the ovary. He performed a double hernioplasty. The ovoid bodies looked so peculiar that he removed the right one for examination, the left one being replaced in the abdominal cavity. The specimen removed was examined by Dr. F. S. Mandlebaum, who pronounced it a testicle. The whole appearance of this individual was feminine; he did not feel justified in ruining her life by pronouncing her a male. He compromised by telling the mother that she might marry, but she would never have children.

Ovarian Pregnancy. — Dr. THOMPSON SWEENEY reported this case. The patient was twenty-six years of age and on Aug. 14, 1916, gave him a history of having been married more than a year, and during that time had taken no precautions against pregnancy. Her periods had been regular, the last appearing July 3, with moderate flow and no pain and lasting four days. On the morning of July 19, she was seized with sharp severe pains in the rectum and right iliac region, spreading to the whole lower abdomen. There was no nausea or faintness. On the morning of July 21 she again had pain which was more severe than before and lasting several hours, and there was some nausea and abdominal tenderness. On July 26 she awoke with much nausea and cramplike pains in the lower abdomen. She improved until Aug. 3, when she was confined to her bed for five days. Aug. 14 she stated that she had had no period since July 3. The uterus was forward and slightly soft. A tumor the size of a lemon was found just to the right of the right uterosacral ligament. Uterine pregnancy was ruled out and the diagnosis of extrauterine pregnancy made. Operation was performed on Aug. 16 and a slight congestion of the uterus was noted. There was some free blood in the peritoneal cavity. A large prolapsed ovary was found on the floor of the pelvis beside the right uterosacral ligament. There were no adhesions. The tube seemed normal and was not attached to the ovary. The blood came from a slight rupture of ovarian tissue, but the fetal sac was uninjured. The ovary was removed. The patient was discharged in good condition Aug. 30.

Dr. CATURANI said he had seen Dr. Sweeney's specimen and considered it one of the most interesting he had seen published. When one had pregnancy of the ovary the follicle could make a good substratum for the growth of the ovum. With the ovum imbedded in the follicle, the successive developing wall of lutein cells would take the place of decidua.

Dr. RABINOWITZ said he had looked at the photographs by Dr. Sweeney and to venture a diagnosis of ovarian pregnancy from a mere picture was rather difficult. The photograph and some facts in the report might as well correspond to a tubal abortion, in which the tube might appear normal and the ovary, as was stated, showed a mere rupture at one point. The photograph might, therefore, be that of a blood clot containing an ovum. The crucial diagnostic points in ovarian pregnancy were: (1) The maturation of an ovum in a Graafian follicle without the presence of decidua; (2) the ovum must be surrounded by a layer of corpus luteum cells. In this report these facts were lacking and not until such pathological proof was submitted could the diagnosis of ovarian pregnancy be made with certainty.

Dr. CATURANI said he might take exception to what Dr. Rabinowitz wanted him to say with reference to the decidua in ovarian pregnancy. One might have in the ovary as well as in the tube what might be called an attempt at the formation of decidua. This would possibly be furnished at the expense of inclosures of glandular tissue in the ovary. In all probability the function of decidua would possibly fall on the lutein cells, with the implantation of the ovum directly into the follicle. It had been well demonstrated that the ovary could take care of the ovum as well as the tube, but neither could do so as well as the uterus.

Chorioepithelioma Following a Hydatid Mole.—Dr. C. F. Jellinghaus reported this case and presented a specimen which was removed from a primipara, twenty-three years of age, who gave a history of a four months' pregnancy. A diagnosis of inevitable abortion had been made. The examination showed the uterus the size of a six months' pregnancy. The cervix admitted two fingers and the patient was having labor pains. Since the mole could be readily felt, the patient was allowed to deliver it; then she was curetted. After this she bled profusely. The hemoglobin at this time was 35 per cent. She remained in the hospital three weeks and there was no bleeding after the second week. She made favorable progress for three weeks when she was suddenly seized with a fainting spell and was found to be in a state of shock. She looked as though she had a ruptured ectopic pregnancy. She was in too poor a condition to undergo an operation at this time. The history of the patient elicited from the husband ruled out the possibility of an ectopic gestation. It seemed possible that a chorioepithelioma had ruptured into the abdomen. The hemoglobin at this time was 27 per cent. The examination showed a cystic mass on either side and chorioepithelioma was strongly suspected. There was no bleeding from the vagina at any time later than two weeks after the expulsion of the mole. Laparotomy was performed. For a few hours before the operation there was a little blood in the urine, and

on coughing the patient brought up a little blood. They felt that this was practically an inoperable case. She was not operated on earlier because of her extremely poor condition. A double ovarian cyst was removed and the patient died three days after operation. About thirty microscopical sections had been made and they all showed a great deal of necrosis and a few typical chorioepitheliomata. One of the cysts was a corpus luteum cyst. This brought up the question whether the pressure of the cyst on the corpus lutem was the original cause of the hydatid mole. Dr. Jellinghaus said there was one thing he wished to insist upon and that was that every woman who had an hydatid mole should be curetted again three weeks after the discharge of the mole. By that time there should be complete regeneration of the endometrium, at any rate no cystic villi should be present. If three weeks after the passing of the hydatid mole a curettage revealed further cystic villi, even if not a typical chorioepithelioma, he thought an hysterectomy was indicated.

Adenomyoma of the Ovary.—Dr. M. RABINOWITZ read this paper which he illustrated with lantern slides. He stated that in his studies of the pathogenesis of adenomyosalpingitis he had arrived at the conclusion that the glanular proliferation which took place in the Fallopian tubes was in the majority of cases due to inflammatory causes. He had now the opportunity of reporting a similar morphological occurence in the ovary, which was in his opinion also the result of infection. This patient, fifty-one years of age, gave a history of having begun to menstruate at the age of seventeen, menstruation being irregular, scanty in amount, and painless. One year ago her menses ceased altogether. She had been married twenty-three years, but had borne no children, though she had miscarried once in the third month. After this she had been curetted and as a result had a pelvic inflammation, which confined her to her bed for three weeks. About five months ago she had an attack of acute abdominal cramps, since which time her abdomen had been growing progressively larger. Palpation revealed the presence of a large, smooth, uniform cystic tumor, which occupied the entire abdomen; its upper limit seemed to be above the ensiform cartilage. Vaginal examination showed the cervix small, the uterine body normal in size and irregular in outline, on account of two small fibroids. The right fornix was occupied by a doughy tumor the size of a lemon, which was fixed in position, being adherent to the pelvic floor and to the side of the uterus. The left fornix was filled with part of the base of the cystic tumor, which filled the abdomen. An abdominal panhysterectomy was performed. The tumor proved to be an enormous cyst of the left ovary, extending upward to the undersurface of the diaphragm. It contained fifteen pints of dark, serosanguinous fluid. The right ovary was converted into a semi-solid tumor, measuring 4½ x 3¼ x 2 in., and intimately connected with the pelvic floor and the right lateral wall of the uterus. The left fallopian tube was elongated and thickened to the diameter of the little finger; it was stretched across to the antero-inferior surface of the cyst wall, and its fimbricated end was occluded and terminated in a cystic, club-shaped dilatation. The right Fallopian tube was also elongated, thickened, tortuous, bent upon itself, and adherent to the posterior surface of the ovary.

The pathological report showed that the large cyst was a cystoma serosum simplex partum papillare. The papillary growths were situated on the inner surface of the inferior wall. Running across the interior of the cyst cavity in its lower portion was a smooth, cordlike structure, a cross section of which presented the characteristic formations of adenomyoma. The fibroids in the uterus also showed adenomyomatous changes. The gland lumina were lined with a low or columnar epithelium; no cilia were to be noted anywhere. In some portions of the section a marked round celled infiltration was present immediately beneath the epithelial lining. The right ovary, semi-solid in consistency, presented an adenomatous proliferation. The areas in the ovary containing these glandular formations had a muscular stroma, which stood out in marked contrast to the connective tissue stroma of the ovary. The lumina of these glands contained old blood and detritus. The ovarian stroma proper showed everywhere evidences of a chronic cophritis. Both fallopian tubes presented the classical morphological changes of chronic suppurative salpingitis.

Analyzing the clinical data in this case the author concluded that they pointed to a genital system below par and that there were strong probabilities of a gonorrheal infection in her early married life. The pathological findings were those characteristic of a slow and insidious destructive process, so typical of the Neisserian organism. The multiplicity of pathological lesions produced by apparently the same cause gave rise to several queries, among which were the following: Why had the fallopian tubes failed to show adenomyatous changes as they did in other long standing chronic types of infection? Why had the right ovary responded differently from the left, undergoing a rather unique morphological change? From whence had the muscle tissue in the right ovary arisen in order to form an adenomyomatous structure? For this two theories might be advanced. One was that of von Recklinghausen, who ascribed all adenomatous changes to congenital displacements and in the case of the ovary it might arise from rests in the Wolffian ducts. The second theory, and the one to which the author was more inclined, was that of Chiary, namely, the inflammatory cause. In this case he thought they had sufficient data to justify this assumption. The right ovary was intimately adherent to the uterine wall; these adhesions were the result of previous inflammatory processes, and some of the uterine muscle fibers might have been carried along, forming "ausseltulpungen," which had been repeatedly observed in the Fallopian tubes, or the muscle tissue might have arisen from the hilus of the ovary, where the peritoneal reflection took place. Dr. Rabinowitz said he was cognizant of the fact that the above explanations did not answer all the questions satisfactorily, yet they were the only ones which he could adduce to bridge over the gaps in the morphopathology in the case presented. As to the rarity of the lesion in the right ovary he stated that he had failed to find a similar record. Phannenstiel stated that fibroadenomatous formations in the walls of ovarian cysts or in the solid portions of multilocular cysts were met with occasionally, but solid adenomas in ovaries which showed no cavity formations either macroscopically or microscopically were a very rare pathological occurrence. Other authorities were quoted showing the rarity of ovarian fibroadenomyomas.

Dr. S. WIENER said there did not seem to be any doubt that the pictures thrown on the screen and the sections under the microscope showed typical adenomyoma, but he wished to take exception to the terminology. Dr. Rabinowitz had called the tumor an adenomyoma of the ovary, and he stated that no such growth had previously been described. It seemed more probable that the adenomyoma had sprung from the ovarian ligament. The ovarian ligament contained smooth muscle tissue just as the round, broad, and uterosacral ligaments did. His idea was that the tumor had grown into the substance of the ovary, mechanically displacing normal ovarian stroma, with which the specimen showed it to be in contiguity. Should this be called an adenomyoma of the ovary?

Stated Meeting, Held May 22, 1917.

DR. GEORGE W. KOSMAK IN THE CHAIR.

Prenatal Care.—Dr. GEORGE W. KOSMAK said that as chairman of the section on obstetrics and gynecology he took pleasure in presenting the program for the evening's meeting. The subject was one that demanded the attention of the physician, the pathologist, the research worker, and that large class of the laity interested in welfare work. It was only recently that an effort had been made to influence the well-being of the child by attention directed to the mother during pregnancy. In the past we had been interested rather in gross developmental errors as shown by fetal monstrosities, and even this study had been marked by speculation rather than careful observation. There was much more to be studied in this prenatal field than gross malformations, and errors in the maternal organism might result in effects on the fetus that did not become evident in this way and might not manifest

themselves until later in life. It was interesting to remember that during the period of intrauterine life, which took up scarcely more than 1 per cent. of man's subsequent Biblical limitation of three-score years and ten, there were crowded a series of morphological changes and developments that were much in excess of anything that occurred subsequent to birth. This was well shown in the paper recently read before this section by Dr. Schumann of Philadelphia, in which he also called attention to the fact that within the short space of forty weeks the microscopical ovum united to the equally microscopical spermatozoon grew to an organism weighing eight or more pounds, with all its viscera and systems of viscera completely organized to maintain life, and further that in this period were laid down the potentialities for the indefinite continuation of the species. It must be evident to every one, therefore, that the relative importance of antenatal life should be regarded as of the greatest moment to the welfare of the race. There were numerous examples which showed the close interdependence of antenatal pathology to postnatal conditions, and it was necessary that more careful attention be accorded to this period than hitherto had been extended to it. The study of antenatal pathology and the diagnosis of antenatal disease was practically a virgin field owing to the fact that observations on pregnant women conducted in detailed fashion had not been a routine procedure. As far as antenatal therapeutics were concerned we were also treading on virgin ground. The importance of the subject of antenatal care was therefore evident, and it was only by calling attention to this need that we could hope to arouse and educate the profession as well as the public.

The Development of Prenatal Care in the Borough of Manhattan.—Dr. RALPH W. LOBENSTINE presented this contribution. He stated that comparatively few women realized either the need or the value to themselves and their offspring of careful oversight from week to week and month to month throughout the period of gestation. This was true not only of the ignorant, but largely so of the more educated and refined. Comparing the death rate due to childbirth in the United States with foreign countries, it had been shown that out of sixteen leading countries the United States stood fourteenth, our death rate in this field being surpassed only by Switzerland and Spain, while Sweden with a total death rate of six to 100,000 stood at the top. The effect upon the child of prenatal neglect was startling. In 1916 in New York City, 12,818 infants died under one year of age; of this number 6219, or 48.5 per cent., died under two months, largely of prenatal causes, including injuries at birth. A study of statistics bearing on the infant death rate shows that 50 per cent. of the deaths during the first year occurred from causes operative before birth. Much of this loss was directly due to the physical strain of too frequent childbearing and too short period of rest after labor. The strain not only affected the mother herself by lowering her vitality, but vitiated to a marked degree the normal development of the offspring. Impressed with the many difficulties surrounding the parturient, with the needless illness and the unnecessary loss of both maternal and infant life, Commissioner Emerson in the winter of 1915 appointed a small committee consisting of Dr. Edgar, Dr. Van Ingen and the speaker to make an analysis of obstetrical conditions in this borough. This small original committee had recently joined hands with Mr. J. H. Lawson of the New York Milk Committee and certain members of New York City Women's Clubs. What they were desirous of accomplishing was: (1) The extension of the efforts in the direction of prenatal work that had already been initiated. (2) The coordination of all the agencies participating in prenatal and child welfare work. (3) The improvement of obstetrical attention at the time of labor. The general situation seemed to offer some perplexing problems. In some sections of the borough there were no obstetrical facilities; in others institutions were too close together; some of these were good, some poor. Many agencies were found to be doing some form of prenatal work, but there was no real coordination. They had therefore begun to look at the needs of the obstetrical community from the standpoint not of the individual clinic nor of a particular society, but from the standpoint of communal interest. They had endeavored to work and plan under the guidance of the Department of Health and Public Charities. A study of the in-service and out-service of the various hospitals made it seem advisable that the city should be redistricted according to hospital facilities if widespread, and more thorough prenatal supervision was to be obtained. There was also no standard as to the quality of the prenatal work done. Dr. Lobenstine presented a map that was marked out in zones, these zones having been mapped so as to include in their boundaries a certain number of so-called health census areas. They had been arranged so as to cause no injury to any hospital service, although they would entail a certain amount of redistribution in each zone. An analysis of the agencies doing prenatal work or those that represented potential prenatal stations was made. There were 127 institutions visited that were doing work of this kind, and they were hoping to win the co-operation of these and to institute a general bureau in each district. In a measure the proper co-ordination of these various agencies was the crux of the whole situation. It was their intention to develop as many prenatal substations as seemed feasible, that was, stations where they would merely examine patients and give advice. They should like to have these stations not more than one and one-half miles apart and they hoped to have at these stations a physician in charge at least twice a week and a nurse on call daily. It was for this purpose that adequate funds would be needed. It should not be forgotten that hospitals reached only 30 per cent. of expectant mothers and that the other 70 per cent were cared for by private physicians and midwives. With such a broad plan in operation they hoped to obtain data sufficient to warrant a further study of such questions as: (1) A uniform birth certificate throughout the Registration Area of the United States. (2) An intensive study into the prenatal and natal causes of still-births. (3) It was high time for a national agitation for higher obstetrical standards and for a gradual elimination of the midwife, although as yet the latter seemed necessary. (4) In a city like New York there was a pressing need for more free maternity beds as well as of improved facilities for respectable obstetric patients in moderate circumstances. These were by no means all the difficulties awaiting solution, but they were among the more important that required investigation. "The State must realize that if it wanted citizens and healthy citizens, it must make it possible for men and women to have families by living a full life themselves and giving a full life to their children. At the present time this was not possible from the top to the bottom of the working class, unless the economic position of the working class family be improved." What was needed here was municipal not philanthropic action. Dr. Lobenstine also submitted a card containing advice for expectant mothers and a plan of the prenatal requirements of the Department of Charities that provided for the proper oversight of each patient.

Prenatal Care, An Opportunity for the Medical Profession.—Dr. A. B. EMMONS, 2d, of Boston read this paper by invitation. He exhibited charts showing the high infant mortality in the United States, the still-birth rate, and the maternal mortality, and stated that the statistics from the United States Children's Bureau as given by Dr. Meigs showed that more women died from childbirth than from any disease except tuberculosis. This mortality rate had been steadily rising; New York City alone among the large cities showed a decline. The mortality of the first month of life came to nearly 40 per cent. of the total to which it was reasonable to add the still-birth rate of about equal amount, though not included in the mortality tables. Reduced infant vitality must also be included in this picture of waste. This was estimated to be equal to eight times the number of deaths. Maternal morbidity would be admitted more readily to be a far larger proportion as compared with maternal mortality. Such was the sum of loss occurring during the time when the obstetricians of the country were responsible for their patients. Conservative estimates put the possible reduction under our present knowledge as one-half. It was the writer's opinion that a profession united in an effort to meet this problem would prevent much more. Lately the attention of thoughtful obstetricians had been turned to preventive measures, such as hygiene of pregnancy,

including the care of the teeth, diet and the whole field of metabolism. A fertile field for research lay open in the influence of pregnancy on the emotions and their relation to toxic conditions. The most important and instructive study of concrete conditions was the report of the Children's Bureau of conditions in Johnstown, Pa. Here it was brought out that family income below a certain scale immediately raised infant mortality. With this went the employment of pregnant women, the poor environment and maternal ignorance. The writer cited authorities showing the inadequate obstetrical care that women of little, and even those of moderate, means received. In Boston, intensive prenatal work was first done by Mrs. W. L. Putnam with a single nurse who visited cases registered for delivery at two maternity hospitals. The success of this experiment was so striking that it resulted in the Boston Lying-in Hospital organizing their own clinic and the Instructive District Nursing Association undertaking similar work throughout the City. The next step was that of establishing special prenatal clinics, one in connection with the Maverick Dispensary, a second in connection with the Peter Bent Brigham Hospital, and a third in connection with the Cambridge Neighborhood House. The obstetric care was given these patients in their homes by graduate physicians with obstetric training who worked under and were supervised by an obstetrician, and who received ten dollars per case. Organized prenatal and obstetric care was thus given independently of medical students, and was therefore available away from a medical teaching center. Davis in the *Boston Medical and Surgical Journal*, January 4, 1917, under the title "The Beneficial Results of Prenatal Work," gave figures and a chart of five wards in Boston. These were based on cases given prenatal care without baby hygiene afterwards. They were compared with other births in the same wards and showed that the saving of babies' lives up to the first year of life varied from 25 to 87 per cent. in the different wards. The method was simple. The patient came to the clinic, preferably when she suspected pregnancy. She was examined and measured and individual advice given before the nurse, who then visited her in her home every ten days. The patient revisited the clinic at intervals. After delivery she received postnatal nursing by these same nurses. The next step had just been started at one clinic, that of having a nurse present at the confinement. The Cambridge Nurse Association had just succeeded in doing this at a cost of two dollars a case, with strict rule that the nurse remain on the case only while the doctor was there. In conclusion, Dr. Emmons said that one of the most potent factors in the loss of life from child-bearing was lack of concentrated and constructive effort on the part of the medical profession to give prenatal and obstetrical care to mothers. The duty of correcting present conditions lay with the obstetrician; to him was open the opportunity to lead.

Maternal Mortality from Childbirth in the United States and Its Relation to Prenatal Care.—Dr. GRACE L. MEIGS, Division of Hygiene, Children's Bureau, United States Department of Labor, Washington, D. C., presented this contribution. She said that the questions which they had been trying to answer were these: What was the death rate from childbirth (including under this term all the complications of pregnancy and labor) in the United States, and how did it compare with that of important foreign countries; was this death rate falling? Did particular factors as nationality, race, rural or urban conditions affect this death rate? There were many difficulties encountered in such a study of vital statistics which made it necessary that statements based on the figures must be accepted with reservation. It was evident that we could accept all figures of the number of deaths and the death rates from childbirth and particularly from puerperal septicemia as being substantially truthful as far as they went, but as giving a gross underestimate of actual conditions. On the other hand, statements comparing the death rates for different years and for different countries were open to question and should be accepted with reserve, as representing the only information now available. The available figures gave no evidence of a decrease in the death rate from childbirth in the part of the United States for which they had records, during the twenty-three years from 1890 to 1913, or during the 13 years from 1900 to 1913, periods which marked an enormous decline in the death rates of certain preventable diseases such as typhoid, diphtheria and tuberculosis, and that of fifteen important countries studied only two had death rates from childbirth higher than the Registration Area of the United States, while one country, Sweden, had a death rate less than half that of this area of the United States. It was a significant fact that childbirth even now in this country was a greater hazard to women of childbearing age than any disease except tuberculosis. The death rate from childbirth was not much less than that of typhoid fever. The figures demonstrated that the whole question of the better protection of women during pregnancy and at confinement was a question of public health protection of the greatest possible importance. It was surely a question which had never received its proper measure of interest from the public or from the medical profession in general. These figures could not be cited as an arraignment of the physicians of this country, though it was undoubtedly true that many women lost their lives because of the lack of training of physicians. The fundamental reason why women in the United States failed to receive their just share of benefit from the discoveries of Holmes, of Semmelweis, of Pasteur, of Lister, and of the great modern obstetricians, was because childbirth was still shrouded by a mist of prejudice, ignorance, and fatalism. Women did not know what sort of protection during pregnancy and at childbirth they needed and had a right to demand. Most women did not seek care as a matter of course early in pregnancy; most families thought an expenditure of money for this purpose unnecessary. In a democratic country all work for public health protection must depend on the support given it by popular interest and understanding. This like all problems of public health protection was fundamentally one of education. The whole subject of childbirth must be removed from the realm of the mysterious and unknown into its true place as a subject about which women had a right to know. It was a question of making our simple knowledge on this question *common knowledge*, of bringing it about that the grandmother or neighbor should advise the young expectant mother to have her urine examined just as automatically as she now advised herb teas of unholy composition. The fundamental problem of providing means for the proper prenatal and obstetrical care of all the mothers of a community was, in the speaker's opinion, the same everywhere. The demand for better care on the part of those interested—women and their husbands—was essential. Beyond this the question of the methods by which this care could be provided was an extremely complicated one compared with which the protection of the health of babies was very simple. Every type of community would have its special problem to solve. Dr. Meigs stated that the Children's Bureau had been making studies during the past year of the kind of prenatal and obstetrical care which women had in different types of communities, in large cities, rural districts, and in various parts of the country. This study had been carried on in Baltimore during the past year and when it was completed would furnish information relating to about 12,000 women who bore children in that city during the year 1915. Letters had come to them from isolated rural districts showing extreme hardship and neglect at the time of child-birth but manifestly could not apply to rural districts in all parts of the country. Investigations in certain other rural districts showed that most mothers had medical care at the time of confinement, but adequate prenatal care was uncommon. Only three out of 50 women had a urinalysis; in only one case had pelvic measurements been made. Yet in a number of these cases pregnancy was not normal; four of the 50 babies were delivered with forceps. None of the 50 mothers had any trained nursing care before or after confinement, yet this particular investigation covered a prosperous and progressive community. Another rural district in the same State showed very different conditions. Physicians were rarely called in confinement cases which were attended usually by farmer's wives, who had acquired more or less experience. They were, however, all without training and charged no fee for their services. Their patients sometimes made them a present of

two or three dollars for their help. No one could make a living by doing this work exclusively in that region. Dr. Meigs also described conditions in a Southern State where in an inaccessible township few women had the care of a physician during confinement. Many of these women had no medical attention not only because of inaccessibility of a physician but because they were unable to pay a doctor's fee. The colored midwives charged two or three dollars for care at confinement, and two dollars a week for nursing services. It would always take a greater push of conviction and public opinion to secure proper prenatal care in the country than in the city. Efforts to secure such care in a rural district had not been made except to a very limited extent in this country. A health nursing service supported by the county would seem to be the logical first step in providing proper prenatal and obstetrical care in rural districts. Through such a service instruction in prenatal care could be given, urinalyses could be made, and cases with symptoms of complications would be found and persuaded to seek medical advice. All mothers could be urged to see a physician at least once as early as possible in pregnancy. A county maternity hospital, even though only a cottage hospital, or beds for maternity cases in a general hospital, would form a part of the plan. Provision for skilled attendance for all women with access to especially skilled assistance for complicated cases would be of course the all important part of the plan. How this could be worked out in inaccessible districts would be the hardest part of the development of such a county unit.

Dr. J. Clifton Edgar said they were not entirely without prenatal clinics in New York. Three hospital services with which he was connected maintained prenatal clinics and were carrying on prenatal work. These were the Obstetrical Service of Bellevue Hospital, the School for Midwives, and the Manhattan Maternity. Although the followup system was as yet imperfect it was gradually being improved. He presented a statistical review of 519 still births that had occurred at the Manhattan Maternity from April 1, 1905, to October 1, 1916. A detailed analysis of the data presented led him to deplore the absence of the routine employment of the Wassermann test in pregnant women. The great lesson which this study taught was the need of antenatal observations and care of the patients. It was difficult to persuade the patients of the upper classes that such care was imperative; it was often impossible to convince the tenement house patient. In this series there were 24 eclampsias and 19 toxemias. These were mostly preventable. In addition there were a number of protracted labors, precipitate labors, and dystocia cases that might have been avoided. All of the syphilitic cases that might have been averted by early treatment of the mother. It was by no means unlikely that at least 100 babies might have been saved, and even this unseemly high mortality might be too small a computation. One of the most hopeless problems confronting them was the elimination of prematurity as a condition resulting in still-birth. Of their 69 cases of prematurity, 23, or one-third, had prematurity alone as the condition of still birth. The tenement house woman was especially prone to abortion and premature labor. This could not be charged up to physical or psychical shock. External injury or shock played little part as a causative factor. Nor could the cause be laid to overwork or physical strain such as the tenement house woman was greatly exposed to. The real underlying cause of prematurity among tenement house women, and this held true to a lesser extent only among the upper classes as well, was the too early getting about after confinement. The prevention of subinvolution in the tenement house woman who insisted on returning to her daily task within a few weeks after confinement, at the moment, appeared entirely hopeless. Allowance must be made for an unborn tendency to fetal death, such as was seen in still births under the most favorable conditions; nearly 5 per cent. of still births were thus explained. These constituted an irreducible minimum which must be taken into consideration in the attempt to reduce infant mortality from still births. The keynote to the further reduction of still birth mortality among the so-called upper classes as well as the tenement population would read "Better general obstetrical care with special reference to prenatal observation."

Dr. J. M. Slemmons of New Haven, Conn., said that the broad question which they had really come to discuss was the better practice of obstetrics. Into the problem various factors entered and it was highly important that they should recognize prenatal care to be one of them. When prenatal care was satisfactorily carried out four things were accomplished: There was a lower death rate among the infants, a lower death rate among the mothers, a larger percentage of healthy children born and the mothers were discharged with fewer gynecological complaints. As Dr. Emmons had pointed out the woman who had been given prenatal care was more likely to receive proper care at the time of confinement, and this of itself justified carrying out all the principles of prenatal care emphasized here tonight. Dr. Slemmons said he was not at all skeptical as to the value of prenatal care; of all the funds given him for running the Department of Obstetrics and Gynecology of the Yale Medical School, 20 per cent. went into prenatal work and the care of patients at the time of labor. They found that it cost approximately fifteen dollars per case to visit these women preliminarily and give them proper care at the time of confinement. The question was where these funds were to come from. They might be given by individual philanthropists or as State appropriations, or perhaps from both sources. At all events they had the problem of where the necessary funds were to come from. However, they could assure donors who would consider devoting their time and money to this work that the returns would be very high. The physician has no higher duty than encouraging individuals to help with this work, the adequate supervision of women during pregnancy, labor, and the subsequent period of convalescence.

Dr. H. M. Larson exhibited charts showing the infant death rate in New York City from 1911 to 1916. During this period the infant death rate had run from 135 per 1,000 births in 1911 to 93.1 for 1916. These charts demonstrated that the milk stations had accomplished definite results, but the milk station had not yet found the infant under one month of age, the period during which the infant mortality was the highest, totalling the number of deaths of infants over one month and under one year. So far as the reduction of the number of deaths among infants under one month was concerned we were practically at a standstill. The members of the New York Milk Commission realized that something must be done for the expectant mother and that in order to care for the infants under one or two months it was necessary to do something for the expectant mother. They had therefore started the experiment of carrying on prenatal nursing of expectant mothers in connection with the work of the milk stations in nine districts. They had also introduced the idea of prenatal care in the health centers. Comparing the supervised cases with the unsupervised cases in the Borough of Manhattan, they found a reduction in the number of still births of 22 per cent. and a reduction in the number of deaths of infants under one month of 28 per cent. in favor of the supervised cases. Out of 3,145 women who received prenatal care there were but five deaths, a maternal death rate of 1.5 as compared with the maternal death rate of New York as a whole of 4.9. Dr. Larson told of the work of the committee appointed by Dr. Emerson to investigate the problem of giving prenatal care to all the people. On studying the problem they had investigated the hospital and dispensary facilities. They found that while hospital service extended from one end of Manhattan to the other there were no restrictions whatsoever as to districts. It seemed that the problem with which they were dealing was very similar to that presented by tuberculosis. That problem was met by districting the city and starting tuberculosis clinics. It seemed that the same principle might be applied to the problem of prenatal care. Dr. Larson presented charts illustrating the way in which the city might be districted following the so-called "Sanitary Areas." Following these same boundaries in a plan for prenatal care would offer the advantage that one could always have the statistics of the Department of Health for comparison and guidance. In their study they had also taken into consideration the location of the hospitals in connection with these sanitary areas and their facilities for obstetrical service. They had found it possible to work out a zoning plan,

but that would require some intensive study to get the most satisfactory arrangement and to see that no hospital suffered. Their organization alone was unequal to coping with the situation; the only way they could succeed was by cooperation. If they could get the different hospitals, dispensaries, milk stations, diet kitchens, Straus stations, and other agencies that had nursing facilities to work together they might be able to work out a plan for prenatal care.

Dr. JOHN O. POLAK described some of the difficulties that he had encountered in attempting to give prenatal care in a clinic started in connection with the Long Island Hospital. He stated that three years ago they had started a clinic and had had 3200 women under their care and followed them to confinement. There was but one death in this series and there had not been a single case of toxemia of pregnancy that had been permitted to go into eclampsia. In order to get into closer touch with the women they not only had an antenatal clinic but a post partum clinic as well. These latter were of great interest. The women came back two or three times and looked upon this clinic as their advisory board. They appreciated the extreme care they were receiving and were willing to allow themselves to be used for clinical teaching. Another thing that had impressed them very much was how little care the public took in this work. Notwithstanding speaking at a number of women's clubs they had been able to stimulate almost no interest in the work, at least so far as financial support was concerned. The public had not been aroused out of the belief that pregnancy and labor was an absolutely normal process. They had been trying to teach that it was not a normal process unless properly cared for under present social conditions; pregnancy was not normal in this country where the blending of races made it more and more abnormal every day. The capacity of hospitals available for maternity cases was still very inadequate.

Dr. HAVEN EMERSON said there was no Section of the Academy which had not been called upon to make some contribution to public health work, and the duty of the obstetrician in this direction had been pointed out very clearly. While it was very certain that the city could not go into obstetrical work, yet he could not agree with what had been said of the hopelessness of the situation when we looked at the uncared for cases and the premature births. It seemed quite possible that they might expect a little help from the city. The city contributed money for the burial of the dead why should it not contribute to the expense of being born, if the cost of being born was only fifteen dollars as Dr. Slemmons said it was in New Haven. But the city could not do these things until the public asked for them. The only way to get these things was through publicity; the Department must wait until certain groups of citizens made known the need and backed it up. It was unbecoming for the Health Department to keep prodding a group of specialists who should take the lead to initiate a program of curative obstetrics. The contribution of the Health Department to this work lay in teaching the value of this service, in directing people to competent practitioners of medicine, and in cases in which a physician was not available to put them in the hands of some one who knew how to be surgically clean; that was one real contribution the Health Department made in its supervision of midwives. Dr. Emerson said he did not believe the hospitals would be unwilling to make the individual sacrifices that might be necessary to such a districting of the city as had been suggested. Voluntary maternity insurance offered another way of meeting the need for better obstetrical care. He thought there had been no greater contribution to a constructive program for public health work than that presented here this evening and he hoped the Section would make itself a committee of the whole and do what might be necessary to further the plans presented. The plan to reach 100 per cent. of obstetrical cases was interesting. The first intensive step in this direction had been made in Manhattan; this was because the social conception of preventive medicine had been developed to a greater extent than in other boroughs.

Dr. JAMES W. MARKOE said the question of obstetrics in New York City was one in which he had been interested for many years. In the teaching of clinical obstetrics he had been almost a pioneer. At the time he had been called upon to organize the work of the Sloane Maternity, obstetrics belonged to the province of general medicine; it was not a specialty and there was but one private clinic teaching obstetrics in the city at that time. After seeing the out-door work in the Boston Lying-in he proposed that the teaching of obstetrics should be augmented by adding to the work of the Sloane Maternity an out-door service modeled after the one he had seen. As this proposal was not accepted he decided to start an independent institution and in 1890 organized the Lying-In Hospital. In the beginning there were associated with him Dr. Lambert, Dr. Edgar, Dr. Flint and Dr. Painter. It had at all times been very difficult to secure money to carry on their work. Dr. Markoe stated that at the time this work was started the cases that came to them came mostly from midwives and were frequently brought in desperate condition. He recalled one instance in which the woman was dead and the child left in with one leg pulled off, and another instance in which two loops of the intestine were pulled down and cut off. These conditions had entirely changed. The percentage of such desperate cases was now small. Doctors were doing much better than they did and midwives had learned to send those cases into the hospital. It was not fair to deprecate the care given obstetrical cases in New York, as it was as far advanced as any other city in the United States in this respect. This question of prenatal care was a question of money and of money only. They now had about 7000 cases a year and the mortality and morbidity were not high. He was sure their educational work among doctors and nurses had given good results. He thought they were also doing a good work in educating the people, and if they could get them to save their pennies and invest in maternity insurance it would be a step in the right direction. He conducted a postnatal clinic every Sunday morning and the patients liked it so well that they asked if they might not come back for information and examination. If the city could be so divided into districts that each lying-in hospital would be able to care for the cases in its particular district it might prove an excellent plan.

Dr. EMMONS of Boston, in closing, said that he wished to say one thing that he thought would be of interest and that was that Dr. Meigs had shown that the maternal mortality had been actually rising, whereas such diseases as typhoid fever, tuberculosis, pneumonia, and diphtheria were still showing a falling mortality. New York was the only large city in this country which had reversed that process and was showing an improvement in the maternal mortality. In 1905 New York showed a maternal mortality per 100,000 of population of 20.3; in 1913 of 14.1; while Boston in 1905 showed a maternal mortality of 14.1 and in 1913, 20.6.

Colloidal Tin in Medicine.—Bruhlet and Michaux have been using intramuscular injections of colloidal tin for furunculosis. In certain cases only the results are surprisingly good.—*La Presse Médicale.*

Exchange of Tuberculous Prisoners.—Through the officers of the respective national branches of the Red Cross the tuberculous soldier prisoners of Italy and Austria-Hungary have recently been exchanged.—*La Riforma Medica.*

Traumatic Periosteoma.—Rocher reports nine cases of this lesion, which is sometimes seen in a small way after a contusion of the shinbone. These are due to the congenital impact of bullets on the bones and are not to be confounded with exuberant callus after fracture or bony formations in the muscles and tendons. They do not undergo involution and persist as osteomas, which may require excision.—*Bull. et Mém. Soc. de Chirurgie.*

The Alkaloid of the Peony. — Holste examined the seeds of the peony for the presence of an alleged alkaloidal base. This occurs as an amorphous, yellowish powder, very hygroscopic, and soluble in water. In laboratory animals tested it increased intestinal peristalsis, produced uterine contractions and constriction of the renal arteries, increased the coagulability of the blood, etc. The alkaloid would appear to be indicated in hemorrhages, especially of the uterus, lungs, and kidneys.—*El Siglo Médico.*

Therapeutic Hints.

Acne.—Edward H. Marsh states that the causes of acne make the treatment both local and general, and that no hard and fast rule can be made covering the internal treatment. Constipation must be corrected; anemia, if present, must be combated, and in general all stimulants, including tea, coffee, and cocoa must be prohibited and if hyperglycemia be found the carbohydrate intake must be decreased. In certain cases it may be protein metabolism that is at fault and must be corrected. If much pustulation be present fresh brewer's yeast given a tablespoonful twice daily internally will have a favorable action. He has found that vaccines bring but little result except in the pustular types of this condition. Local treatment is absolutely indicated in all cases. Preliminary to the use of medicinal applications, the affected parts must be scrubbed with water as hot as can be borne, and Ivory soap; where the skin is thick and greasy, tincture of green soap may be used, and in some of the more sluggish types a sulphur and sand soap is of value. After the use of soap and water the soap is to be rinsed off with hot water then to be followed with an application of cold water for five minutes. The more acutely inflamed the condition the milder the medicinal application. The time-honored calamine lotion may be then used:

℞ Calaminæ precipitatæ.
Zinci oxidi, aa.....℥j.
Aquæ calcis.....℥iv.

The application most often used is:

℞ Potassii sulphuretæ.....℥j.
Aquæ .....℥ij.
℞ Zinci sulphatis.....℥j.
Aquæ .....℥ij.
M. et adde sulphuris precipitati.....℥j.

Ointments may be used in place of lotions and the change is often beneficial. The following ointment answers the purpose:

℞ Acidi salicylici.....gr. x.
Resorcinolis .....gr. xv.
Sulphuris precipitati .....gr. xx.
Petrolati, q. s. ad.....℥j.

If the skin begins to scale from the use of any of the above a mild cream may be used instead for a day or two. Surgical treatment may be needed weekly by expressing comedones by means of the curette-shaped comedo extractor. Pustules should be opened with an ophthalmologist's cataract knife, while curettage of the deeper pustules is of great benefit but necessitates confinement of the patient for a few days following the procedure. Scar formation may occur from deep-seated lesions and the treatment of acne is necessarily a prolonged one.—*Medical Times.*

Southern Treatment of Malaria.—George H. Walter considers that in the treatment of malaria as in all acute febrile conditions the alimentary tract must be cleansed, the kidneys flushed, the liver stimulated and quinine pushed to physiological effect. Calomel in relatively large doses—three to eight grains a dose in ordinary cases and twenty, thirty, or even to fifty grains a dose in the pernicious forms. These doses are followed in about three hours by a saline laxative. Often it may be necessary to inject ¼ grain of morphine fifteen to twenty minutes before giving the dose of calomel in order to quiet the stomach for retention of the drug. If nausea is not allayed cloths wrung out of hot water may be applied over the stomach and a cold wet cloth placed around the neck. If temperature is high, the body may be sponged freely with tepid water. Follow this with the defervescent compound, a dose every fifteen to twenty minutes, for four or five doses, or give a small dose, ⅛ grain of pilocarpine, repeating in one hour if not sweating.

If the pulse is bad, nitroglycerin, 1/100 grain hypodermically gives the best results. If the pulse is weak add strychnine. To flush the kidneys give citrate or acetate of potassium, five to ten grains of either (or less) every three hours in plenty of water. If the first dose of the laxative saline does not work quickly, in three hours, a second dose must be given. Should this not prove effective in two hours, administer an enema of salt solution. The best laxative salt is one which effervesces, as effervescent combination of epsom salt, lithium carbonate and colchicine, or citrate of magnesia, one-third of a bottle every hour is more easily retained on the irritable stomach. As soon as the temperature is reduced and the eliminative organs working freely —all danger of congestion passed—quinine bisulphate, five grains every half hour or hour, must be given for three or four doses until the ears begin to ring—physiological limit reached. After six or eight hours give ten grains more in two doses an hour apart. After twelve hours give fifteen grains more, in three doses an hour apart. Thereafter, five or ten grains night and morning for three days. In a malarial district give five grains night and morning on the sixth and seventh days of the week for three weeks. If the patient is comatose or if the stomach is too irritable to retain quinine by mouth, give from three to six grains hypodermically, and repeat as indicated until the stomach is able to retain the quinine. The quinine-urea hydrochloride comes in tablets and is quite soluble. The injection may cause some local inflammation, so care must be taken. Warburg's tincture, one dram three times a day, and an iron tonic containing arsenic and strychnine, taken for a week or two following cessation of the fever, gives excellent results, according to Walter. So also does cacodylate of soda at this stage.

In the hemorrhagic form of malaria (hematuria) emetine one to two grain doses hypodermically to be repeated in from four to six hours has remarkable effect. When the sufferers are left with a torpid liver as a result of malaria, podophyllin, phosphate of soda and corresponding remedies are useful.—*Clinical Medicine.*

Hypodermic Treatment of Malaria.—B. F. Terry states that the hypodermic injection of quinine and urea hydrochloride for this condition produces much better results than when quinine is given by mouth as there is so often a coagulated condition of the stomach and bowels and therefore little or no absorption of medicine from these organs; consequently whenever quinine has failed to prevent a chill, the blame may be laid to the nonaction of the stomach. As in the above he gives first a real calomel purge—that is, from ten to 100 grains as the urgency of the case demands, and then the quinine hypodermically.—*Clinical Medicine.*

CERTAIN TECHNICAL REFINEMENTS IN METHODS OF INTRAVENOUS INJECTION.

BY JOHN H. STOKES, M.D.,

MAYO CLINIC, ROCHESTER, MINNESOTA.

THE administration of salvarsan does not ordinarily appeal to practitioners as an affair of special technical detail, and, as ordinarily performed, it probably does not answer to that description. It was, therefore, with considerable interest that I heard one of the speakers at the recent meeting of the Public Health Administration Section of the American Public Health Association comment on the effect which multiple punctures, incisions, infiltrated arms, and other accompaniments of an unsuccessful and amateurish intravenous technique have on patients for whose treatment repeated salvarsan injections constitute a desideratum from both the

FIG. 1.—Correct positions of operator, nurse and patient. Schreiber needle technic (original salvarsan).

medical and social standpoints. I, myself, have been impressed from time to time with the undesirableness from the technical standpoint alone of committing to the care of inexperienced internes, house physicians, and practitioners, the salvarsan therapy of syphilis. Even the poor can scarcely be expected to submit with good grace to repeated barbarities offered in the name of medicine. In easy cases almost any technique suffices. But in difficult cases, to give injection after injection into a single available vein concealed below a cushion of fat, without resorting to incision to reach it, becomes a technical accomplishment of no small magnitude.

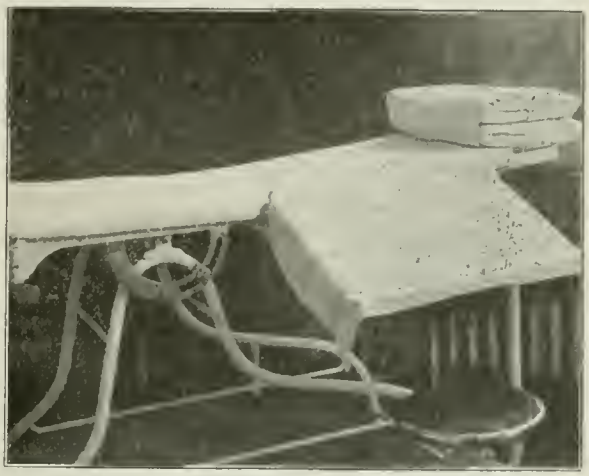

FIG. 2.—Bedside table used as a very satisfactory rest for the arm.

On my own service there has been gradually worked out a technique which, in our hands at least, has greatly reduced the percentage of technical error. The requirements of this service from the standpoint of technical ability are high, since the clientele consists of pay patients of at least average intelligence, and with quite definite conceptions of the type of service they should receive from a specialist. About four thousand injections of salvarsan are now being given yearly, which makes the pressure of the work such that the technique must be, not only smooth, but rapid, and yet free from slapdash and short-cuts for the sake of speed. The technique here described seems to have the advantage that it can be rapidly acquired by a relatively inexperienced operator, and while it is definite, it is reasonably elastic and adaptable to the variety of conditions met in intravenous work. Injections are given by the Chief and the first assistant, although other medical members of the staff may witness the procedure and learn the method on occasional easy arms. It is its applicability to difficult cases which seems to justify the description. The general principles governing this part of the work are as follows:

No salvarsan is given to ambulatory patients. Each must remain under observation in the hospital

for at least twenty-four hours. From 60 to 80 per cent. of our injections have been of original salvarsan or arsenobenzol, and the balance of neosalvarsan. Strict asepsis is part of the operating room technique, and the reagents used in the preparation of the drug conform to the original Ehrlich criteria or standard modifications.

Water redistilled from Pyrex and Jena glass and boiled, is used in all injections. Neosalvarsan is given by the Ravaut method, slightly modified, each decigram of salvarsan being dissolved in 1 c.c. of water, and the dose administered with a Luer syringe. Salvarsan is administered by gravity flow, a concentrated solution containing from 4 to 8 doses being prepared (0.6 gm. in 25 c.c. of the water), and diluted after neutralization and before using, so that 0.6 gm. of the drug is contained in 100 c.c. of the solution. A single graduated container is used, which is suspended from a standard where it is kept throughout the morning's work. The tubing of the container is filled before beginning with distilled water to exclude air, but this water is allowed to escape before the first injection is given, so that only salvarsan enters the veins. The glass-

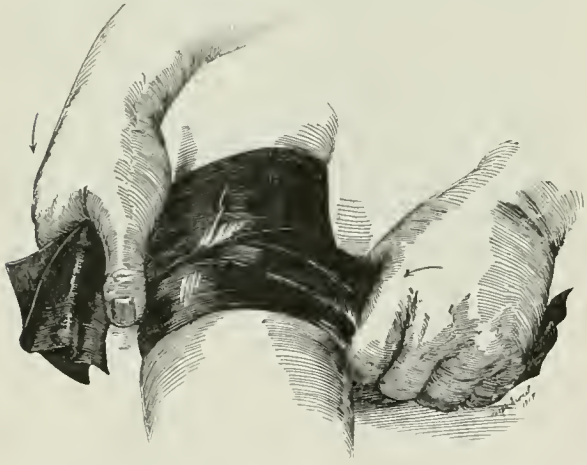

Fig. 3.—Correct appilcation of the band tourniquet to the left arm (Esmarch bandage). The nurse stands at the patient's left shoulder. The tourniquet is pressed downward by the hands, instead of exerting traction.

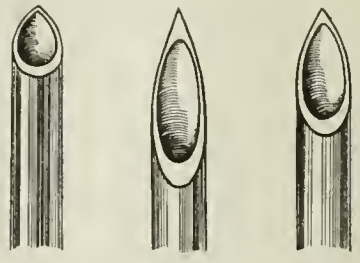
ware is boiled in distilled water. The needles and the salvarsan ampules are sterilized in 95 per cent. phenol followed by alcohol, and the needles are rinsed in redistilled boiled water, in order to avoid the use of disinfectants containing metallic salts, such as bichlorid. Gloves are sterilized by boiling and are put on dry.

The indications and contraindications for the use of salvarsan and neosalvarsan need not be discussed in a technical paper, further than to say that in my experience the effort to reduce the technical difficulties of the administration of original salvarsan by the use of concentrated solutions as recommended by Brayton (*Jour. Am. Med. Assn.*, 1916, lxvi, 1921-1922) has not been entirely satisfactory for general use. It is valuable when one or two injections must be given unaided, but with the assistance of even an amateur or an office girl it is unnecessary. Even with the most careful neutralization, the drug seems to be distinctly irritating, and its injection, epecially if the solution is at all hot, may cause collapse. The injection must be made very slowly indeed in large veins, and in small veins there may be intense pain and subsequent thrombosis without subcutaneous infiltration. The method seems to be unsuitable on this account precisely where the technical difficulties are greatest—in wrist and hand veins, and where only one or two unsatisfactory veins are available



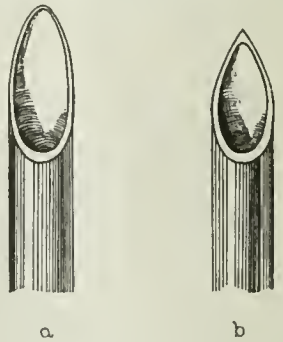
a b c

Fig. 4.—Three types of needle point: (*a*) too short, (*b*) too long, (*c*) correct.

for a series of injections. The technique to be described has been used on my service in administering amounts of solution up to 100 c.c. with a large Luer syringe, so that concentrated solutions have been discarded entirely in the case of original salvarsan, and there seems to be no difficulty in meeting the indication both in children and adults.

The duties of a nurse or assistant are confined to unsterile manipulations to which even the inexperienced may be easily trained. These manipulations consist in preparing the patient, managing the tourniquet, releasing and closing the tube-clamp in the case of original salvarsan, and pressing a sterile sponge over the point where the needle enters the vein, at the time the needle is withdrawn and then bandaging the arm. The only manipulation calling for any skill is the application of the tourniquet. The preparation of the patient includes the following:

A light breakfast is eaten(tea and toast); the temperature, pulse and respiration are taken before the patient enters the operating room. The left arm, preferably, is prepared with tincture of iodine, which is then partly washed off with alcohol, so that the color does not conceal difficult veins and so that dermatitis may not ensue. In very difficult arms an alcohol compress may be used after soap and water cleansing. The arm and shoulder should be



a b

Fig. 5.—(*a*) Rounded needle tip, with cutting edge, which makes an incision in the vein instead of a puncture. Less desirable than (*b*), the pointed needle, which inflicts less trauma and diminishes the possibility of leakage.

bare and the neck uncovered since the slightest constriction may hold the drug in the vein and favor thrombosis. A marked constriction concealed by the shirt sleeve may cause a leakage around the large needle.

One of the seemingly trivial elements in the giving of an injection, but one which should be rated very high, is the confidence and cooperation of the patient. Operating under a general anesthetic, or under a local anesthetic, one seldom realizes the

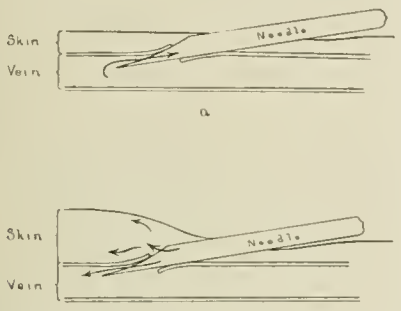


Fig. 6.—Illustrating the effect of partial puncture of a vein, with a long-bevel needle; (*a*) return of blood has been without completely entering the vein; (*b*) infiltration of the subcutaneous tissue even after a return of blood has been secured, as soon as injection is begun.

psychic effect on the operator of a nervous or distrustful patient. Panic may seize even the fairly experienced if the goal is not reached on the first attempt; the tense attitude, the shrinking away, the sounds of remonstrance and disapproval from the patient are only too efficient in bringing beads of sweat to the operator's forehead and in damaging the fine movements of the hands on which his success depends. To stop to cool off may only make matters worse, and to fail entirely is to damage his nerve in subsequent work more seriously than is realized. For these reasons I insist that the atmosphere of the operating room shall be as carefully prepared as that of a social salon. The new, nervous patient having already met the chief and his first assistant is relieved of anxiety as to who is to treat him. He, or more often, she, is met with smiles, addressed by name, and treated as a friend from the moment she enters the office and the operating room. She finds herself on the table in a current of casual conversation, good humor, and friendliness which relieves her anxiety. Other patients to whom she may have spoken have conceded that it doesn't hurt. We do not use large needles without preparing for them by local anesthesia, in which we can use the finest hypodermic needle. I am firmly convinced that anoci-association, which after all is simply a putting of one's self in the patient's place, is an essential ingredient of a technic which is to work day in and day out without a hitch. Patients who have never been either hurt or scared approach one with the calm-inducing lack of fear with which animals that have never seen a man disarm their human enemies.

Lighting.—The operating room should, if possible, be so arranged that the arm is cross-lighted rather than longitudinally or from above, since with the latter illumination especially, the elevation of the skin caused by the vein casts no shadow and is correspondingly difficult to see. Light containing much yellow or green, whether from walls, artificial lighting or shades, may conceal an otherwise visible vein.

Patient.—The patient lies on the table, arm extended at full length at right angles to the body and resting with the palm of the hand on the slanting bedside table which I have adapted to this purpose (Figs. 1 and 2). This is a strategic position for the administration of an intravenous injection. The patient is at rest. The full arm is extended for a survey of the situation. The carotid and jugular pulsation, the larynx and conjunctiva, and the upper thorax are all in the line of vision, so that the operator himself can follow every change heralding an acute reaction—the acceleration in pulse, the slight uneasiness, the gulp, the sudden catch in the breath, the flush beginning at the clavicle and running upward, and the engorgement of the conjunctiva. It is impossible for him, without willful neglect, to continue an injection until he discovers, as he rises and secures a full view of the face at the end of it, that the patient is rapidly becoming livid and pulseless.

Tourniquet.—It is my practice to use a soft band tourniquet, made by folding double a three-inch rubber Esmarch bandage. Thirty inches is an average length. It is used unsterile by the nurse or assistant, who should be taught the following points:

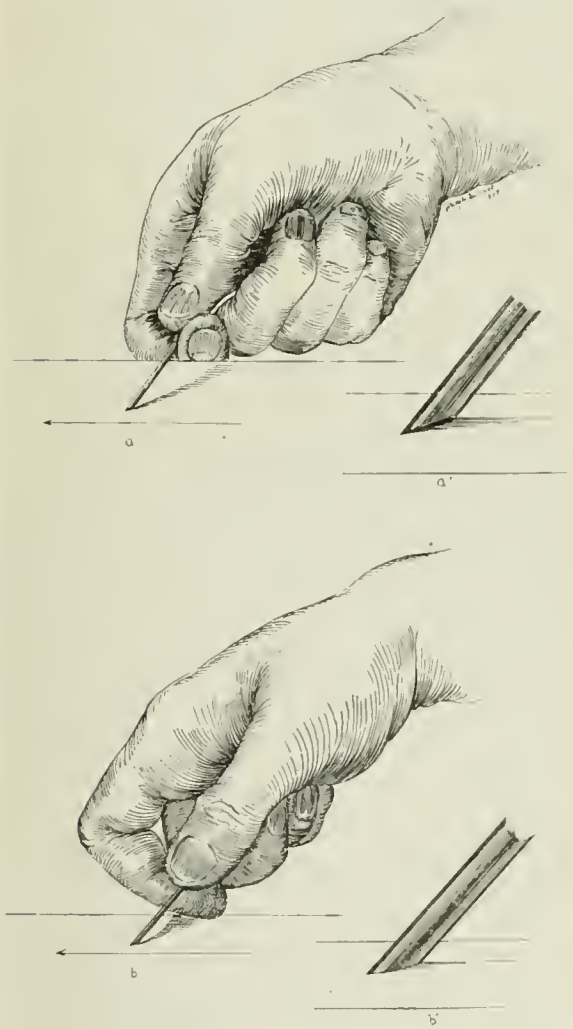

Fig. 7.—Retouching a needle on an oilstone to secure the pointed tip illustrated in Fig. 5. (*a'*) (*b'*) Viewed from the side. The strokes are made in only one direction—away from the operator.

1. To apply it flat, wrapping and not twisting it around the arm. The two ends pass each other on the flat, so that the effect is that of a cuff rather than a cord (Fig. 3). This minimizes the discomfort to the patient, and promotes the maximum of

surface compression with the least compression of the deeper arterial supply. It also prevents the escape of the vein to be injected under the crossing of the two ends, which occasionally results in the imperfect distention of difficult veins.

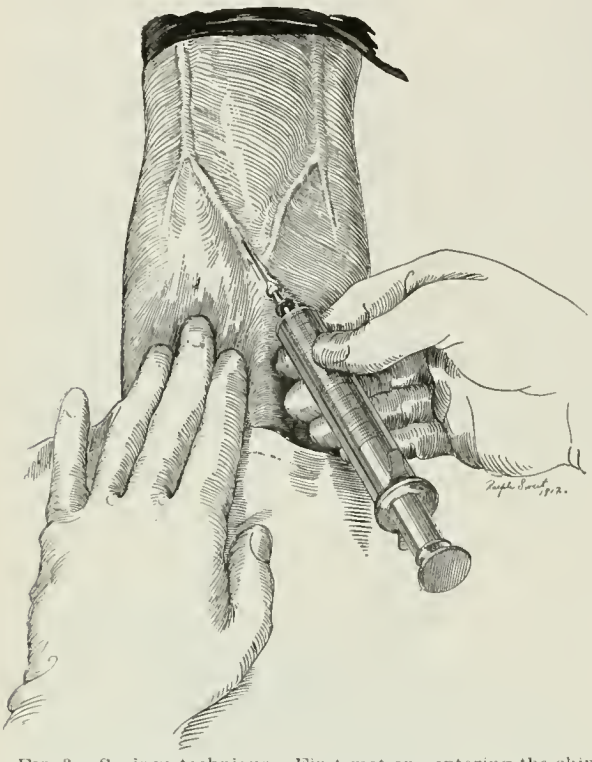

FIG. 8.—Syringe technique. First motion, entering the skin, showing the tension exerted by the left hand to fix the vein and the pressure with the right for the purpose of steadying the syringe. The needle point is visible under the skin, directly over the vein.

2. Two hands should be used in holding the tourniquet, and the release should be without twist or jar, and without unsterilizing the field.

3. The skin should not be pulled aside or twisted on the arm in applying, since the effect is to flatten the vein and render it less palpable and visible.

The Vein.—Certain seemingly obvious details are easily overlooked. A survey of the situation before rather than after an attempt at puncture is essential. In the difficult arm, I am inclined to rate palpation above inspection, and for that purpose, a single finger should be trained to the acme of tactile acuteness by constant practice. The ball of the middle finger of the left hand is especially serviceable because it has not been rendered insensitive by the trauma to which the other fingers are subject. Cross stroking with this trained finger will detect a deep vein where nothing is visible. By light palpatory downward pressure, its caliber and fixation may be estimated. Thrombosis from a previous injection not infrequently is to be detected before entry only by palpation, since the vein may remain of the same caliber at the site of thrombosis as in the normal portion. A vein which is not sclerotic and yet rolls sharply under the finger is very apt to be thrombosed.

A variety of devices can be employed to distend difficult veins in addition to the customary clinching of the fist. The most easily available is the slapping of the skin over and around the vein with the flats of the fingers producing a temporary paralysis of the vein wall. This is of so much assistance that I employ it as a routine, since a well-distended vein is better fixed than one less distended. A sharply slanting support sometimes assists in securing an effect. Hot applications are of great value in difficult cases, but are time-consuming unless the patient has been told to soak his arm before coming to the operating room. This method is also useful in distending small scalp veins.*

The angle of the vein should be carefully estimated and the depth considered before a puncture is made, especially when the needle is to be advanced well beyond the point of puncture as in the technic here described. Veins in obese women which show as faint bluish patches at the flexure are apt to be more superficial than one is led to expect, and are likely to be transfixed by over-energetic or jerky operators. The fixation of veins in the connective tissue is a more important factor at times than their caliber, and the thickness and toughness of the skin over a vein is equally important. For example, it is often easier to enter a small well-fixed superficial vein at the flexure of the elbow

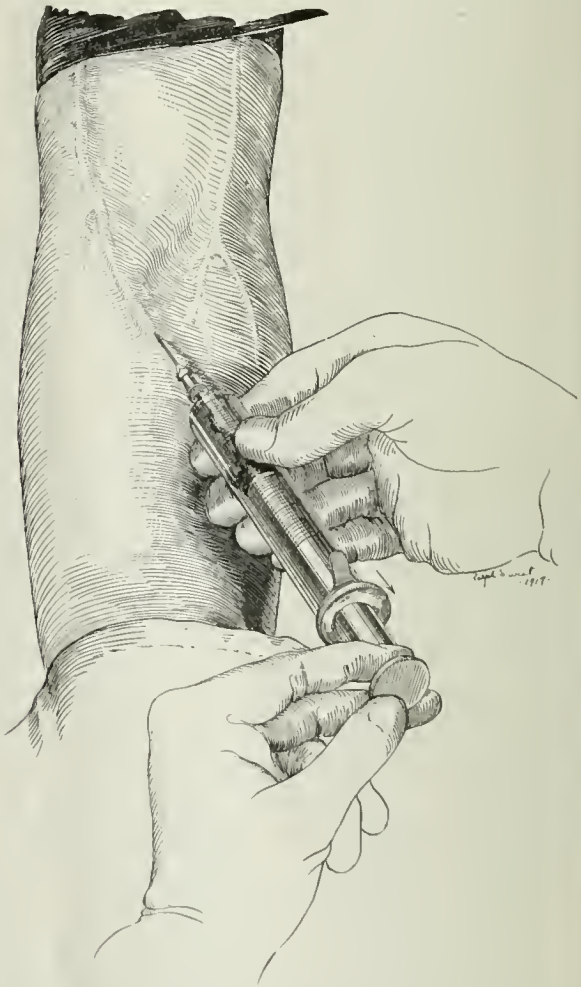

FIG. 9.—Syringe technique. Needle has been advanced, and return flow tested by pulling on piston. A stream of blood should shoot across the fluid if a proper entry has been made. The right hand maintains its pressure.

*My attention has been called by Dr. Jay Frank Schamberg to the value of daily gymnastics in developing previously small arm veins.

than to enter a vein three times the size at the condyle or in the tough loose skin of the radial side of the wrist. The most difficult vein in my experience is the sclerotic vein of the sun-tanned old man, which has lost its fixation through atrophy of the

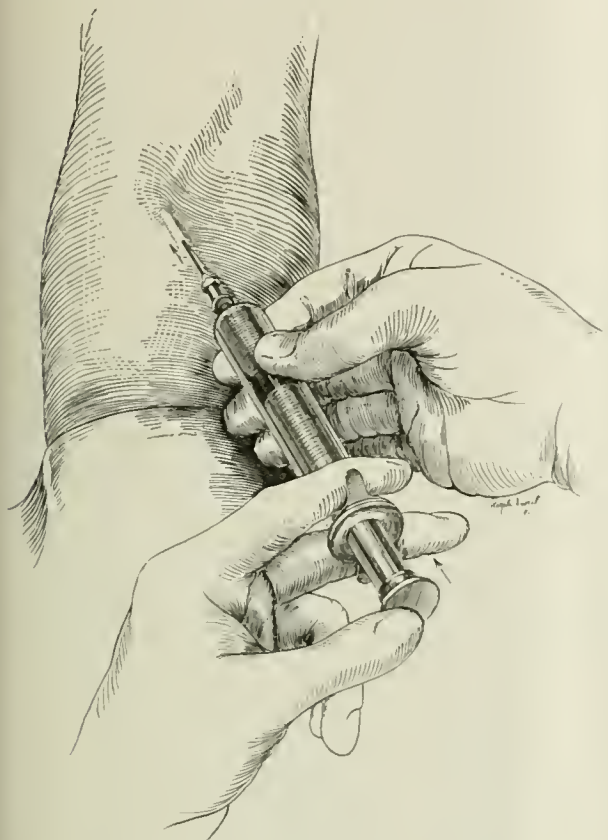

Fig. 10.—Syringe technique. Injection

connective tissue. Veins on the back of the hand sometimes tempt an operator to his sorrow although on occasion they are valuable. The more movable the vein and the tougher the skin, the smaller the needle that should be employed. The point of entry on a vein should be as near the operator and as far from the heart as possible since hemorrhage from a mispuncture may be controlled with a finger, while a second puncture may be made farther up a vein if it is the only one available. The risk of thrombosis is thus diminished by avoiding the passage of an irritating solution over a point of trauma.

Needles.—Close attention should be given to the type and care of needles. In general, I may say that in my experience a series of failures in the hands of a reasonably competent operator is most often attributable to a dull needle, despite the shop maxim that a "poor workman always blames his tools." An improperly sharpened or dull needle jerks, strips the vein, tears holes, or transfixes.

In Figs. 4 and 5 are indicated what seem to me essential points in the needle to be used for intravenous work. The bevel of the majority of needles when first purchased is too long, and by incorrect sharpening they soon tend to become too short. The long blade-like point of the flat-beveled needle is an unknown quantity once it has passed out of sight and is too often embedded in the far side of the vein wall before it seems fairly through the skin. Then follows unexplained leakage and futile efforts to retrieve the lost advantage or to advance the needle farther up the vein. If injection is begun because a good flow of blood has been obtained with a long bevel needle, an infiltration is apt to occur, the mechanism of which is explained by Fig. 6. Flat bevel needles are more easily shut off against the top of the vein than shorter bevels and confuse the operator into thinking he has failed. The ease with which a long blade-like point enters the skin makes it very attractive to the novice and often betrays him into difficulties. The defect of the short bevel, which strips the vein without entering it, or tears a hole, is obvious.

The desirable and undesirable type of needle point is illustrated in Fig. 5 and the method of honing a needle on an oil stone to obtain it is shown in Fig. 7. Most needles on resharpening lose the point put on them in manufacturing, and develop at the hands of the average sharpener what is fallaciously supposed to be a cutting edge instead of a point. This inflicts greater trauma on the vein, makes a larger opening for subsequent leakage and does not "take hold" as well as a needle whose mode of action is to puncture rather than cut.

The gold needle has largely displaced the steel needle in our work and the care of the needle is greatly simplified by doing away with rusting. Tempered gold needles are cheaper than platinum and retain their points reasonably well. They do not leave the brownish tattoo stain in the skin that even a slightly corroded steel needle will leave. For routine syringe technic the 1 1-2-inch gold Luer needle, 20-gauge, attaching directly to the syringe, is satisfactory. The steel hypodermic needle, 22- or 24-gauge, is very useful when a very minute and delicate vein at the wrist or on the forehead, is to

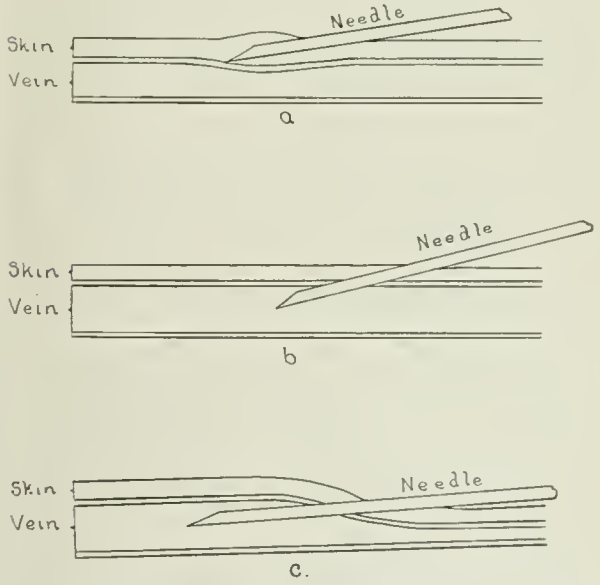

Fig. 11.—Sagittal sections showing the successive positions of the needle in the technic illustrated in Figs. 8, 9, and 10; (*a*) entering the skin above the vein; (*b*) angle for entering the vein; (*c*) advancing the needle after entering.

be entered. It should not be resharpened, should be sterilized in phenol and alcohol, should not be used more than three or four times, and should not be more than 1-2 inch in length, otherwise it may be difficult to secure enough return of blood to

demonstrate that the vein has been entered. Through such a needle on a large Luer syringe I have given 50 c.c. of fluid.

For the injection of the larger amounts of fluid by gravity our preference is for the Schreiber

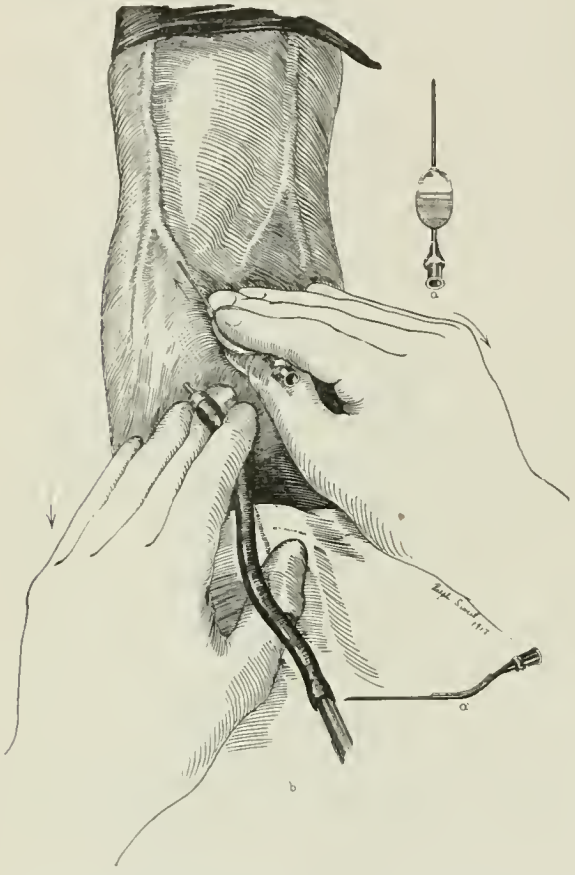

Fig. 12.—(*a*) Front view; (*a'*) side view, Schreiber needle; (*b*) Schreiber needle technique. First motion needle entering skin. Tension exerted by the last three fingers of both hands. The needle is steadied against the tip of the middle finger, and the entry made by depressing the knuckles rather than by advancing the hand.

needle (Fig. 12) in 17- or 18-gauge. Gold needles of that type may be obtained on order and those in use on my service, while bending rather easily, have given satisfaction.

The advantage of the ordinary filter pump or aspirator for the cleaning of needles with water, alcohol, and ether by suction deserve special mention, when much of this work is being done.

The Syringe Technique.—For this technique the needle is attached directly to the syringe since this does away with the uncertain grip of the fingers on a slippery needle while doing what should be an exact operation. The barrel of a syringe is so much more controllable than a needle that it is now our practice to introduce smaller needles for the gravity method, by a syringe, which is then detached. The needle is always entered bevel up. Four details are essential to the technic. First, the syringe is held flat on the palmar surface of the four fingers of the right hand, which form a broad bed upon which the syringe is firmly held with the thumb. Second, the movements of the hand and syringe are controlled and the jerk and the unsteadiness can be entirely prevented by firm pressure with the back of the fingers of the syringe-hand on the patient's arm. Third, tension on the skin with the left hand as shown in Fig. 8 fixes the vein and prevents heaping of the tissues ahead of the needle, with stripping of the vein and a jerky puncture. Fourth, two separate movements, one to enter the skin and one to enter the vein are essential. The two-movement entry prevents the jerk and over-reaching which is apt to follow the attempt to pierce a soft tissue lying behind a tough one.

The application of these principles is illustrated in Figs. 8, 9, 10 and 11. The needle should be used with the bevel toward the graduations of the syringe so that the dosage can be watched. Entry is made directly over the vein and the first movement carries the slightly inclined needle 1-4 inch into the skin over the vein wall, where it is visible as an elongated wheal and may be palpated in difficult arms or deep veins. Downward pressure with the whole right hand, syringe and needle, now dimples the top of the vein and a very slightly increased slant carries the needle through the wall with a barely perceptible advance. The pressure of the syringe-hand on the arm is now increased enough to bring the needle practically horizontal and it is then advanced half its length up to the vein and remains stationary. The tension on the skin with the left hand is released as the needle is advanced. The broad base by which the hand controlling the syringe rests on the arm, effectively prevents "creeping up" during the injection, with possible puncture of the far side of the vein. The running

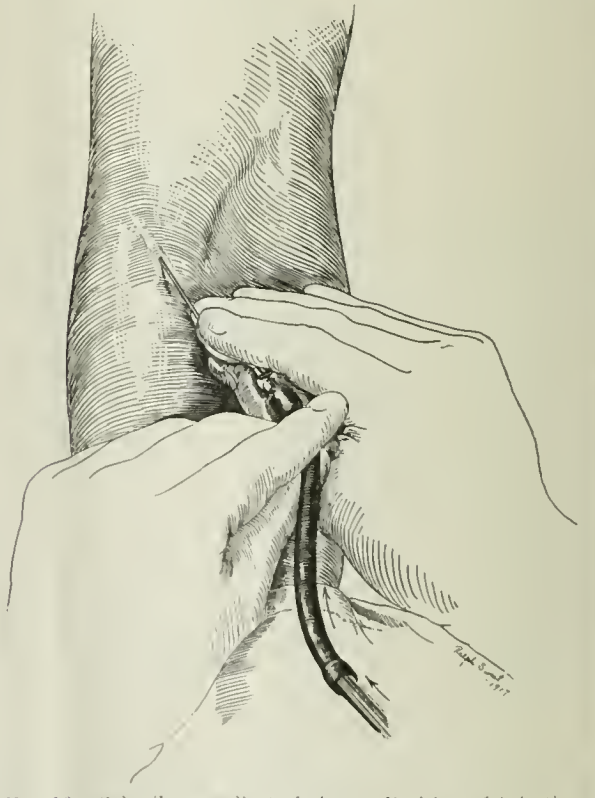

Fig. 13.—Schreiber needle technique. Position of injection. As injection is completed the tubing is compressed just back of the shoulder and the needle withdrawn as a sponge is pressed over the point, without disconnecting.

of the needle above the site of trauma is, to my mind, instrumental in reducing the likelihood of thrombosis.

With the needle in its final position, the operator pulls back on the piston with the left hand (Fig. 9).

If a successful entry has been made, a spurt of blood shoots across the clear fluid in the syringe, and the injection may be begun. If this test is applied *invariably* before the piston is advanced, and repeated once or twice during a difficult injection, the percentage of infiltrates with the syringe technique can be reduced almost to the vanishing point.

The Schreiber Technic.—I have previously called attention to the value of local anesthesia in the introduction of large needles into veins, and further experience has only convinced me the more completely that this detail is essential to the giving of an intravenous injection of original salvarsan *secundum artem.* One minim of a 2 per cent. solution of cocaine seems to be devoid of danger and acts so quickly that it causes no delay. The introduction of the needle then becomes an exact procedure rather than a haphazard stab. The patient does not disturb the procedure by shrinking away or wincing. His confidence in the operator is not subject to test. The same principles are used as in the case of the syringe technic. The Schreiber needle is held like a pen (Fig. 12), however, since it is then steadied by two fingers instead of one, and since the position of the hand seems to be more natural after the needle is entered, and must be maintained for a longer time. Pressure on the arm with the right hand and tension on the skin with the left are again essential. In doing this final step, the needle should not be held rigidly. The right hand should relax and the needle be guided by thumb and forefinger rather than forced up the vein. The needle should be run up the vein as in the case of the syringe technic. The movements of the needle in entering suggest those of vertical penmanship, and are accomplished by depressing the knuckles, keeping the wrist fixed, rather than by moving the hand. The needle is introduced detached, and after a free flow of blood is secured the adapter is inserted by the left hand and the injection begun (Fig. 13). The needle should not be released or the right hand moved in difficult veins after the beginning of the injection. There should be a tell-tale in the tube near the needle to show the presence of air, although it is surprising what large amounts may enter a vein without ill effect.

A summary of rules of thumb is appended to be applied seriatim if with either technic a free flow of blood through a needle after introduction or a free flow of fluid into the vein cannot be obtained.

1. Depress the point of the needle without advancing. The bevel may be shut off against the top of the vein.

2. Palpate the point with the free hand. It is easily recognized if it is still above the vein.

3. In using a syringe, twist the piston in the barrel, pulling backward. It may be stuck.

4. Slowly withdraw the point, if it cannot be felt above the vein, lifting up as you do so. If it has entered the opposite wall it usually comes away with a palpable snap. Then quickly advance again, pressing down hard against the arm with the back of the syringe hand and lifting the point, to flatten the angle of the needle to the vein.

5. If the above procedure fails twice, withdraw the needle until the point is just short of the skin puncture, and advance again after repalpating the vein. This is a last resort.

6. If the fifth procedure fails on one or two trials, withdraw the needle entirely and do not reintroduce it until you are satisfied as to its point, and that it is not plugged. Pressure on the vein for five minutes with elevation of the arm while this is being done will often enable you to use the same vein again.

7. Make no comments audible to the patient regarding the condition of your needle.

8. Never try to inject through a hematoma. Use another vein or stop.

9. Never inject and ask if it hurts, if you have the slightest reason to suspect that it will. To inject a little to find whether you are in the vein or not is absolutely inexcusable.

10. Make every effort to have one puncture suffice, using the needle in various directions through the same puncture.

In withdrawing Schreiber needles from veins the aspiration of blood back into the tube by lowering the container, or washing the needle out with salt solution from a separate cylinder are unnecessary. Pressure made by the nurse over the needle as it is withdrawn, and the shutting off of the stream just back of the adapter and not higher up the tube, will prevent any leakage. After injection the needle can be rinsed by drawing distilled water through it or the elastic recoil of the rubber tube will cause some of the solution to spurt through it when the compressing finger is released. It goes without saying that needles and solution should be fresh when used on clean patients or suspects, and that patients in florid stages should be treated last.

The administration of intravenous medication to small children can be accomplished with ease as a rule through the external jugular vein, or through the anterior auricular or the more prominent scalp veins in heredosyphilitic babies. We have thus far found this technic applicable to all cases and have had no occasion to attempt an injection into the superior longitudinal sinus through the anterior fontanelle. In all work with small children, fine steel hypodermic needles should be used.

ADENOMYOMA OF THE RECTUM.*

By FRANK C. YEOMANS, M.D., F.A.C.S.

NEW YORK.

SURGEON TO THE CENTRAL-NEUROLOGICAL AND WORKHOUSE HOSPITALS, INSTRUCTOR IN SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

WHILE both the benign and the malignant growths of the bowel, originating in the mucosa, have long been observed and thoroughly studied, as yet comparatively few observations have been made upon tumors occurring in the muscular coats.

In 1910, Descoudres[1] reported from the literature 80 cases of myoma of the intestinal tract, sixteen of which were in the rectum. These tumors are either internal, projecting into the bowel lumen, or external, growing away from it. He reported only twelve of the external variety. They are very large and their diagnosis is difficult. In the case of Descoudres the tumor was the size of a cocoanut, presented at the buttock and made sitting difficult.

Last year Cullen[2] reported fifteen cases of adenomyoma of the rectovaginal septum. Of these 5

*Presented at the nineteenth annual meeting of the American Proctologic Society, New York, June, 1917.

were his own, Stephens 5, Jessup 2, Lockyer 2, and Nadel 1. Recently Kellogg[3] has reported a case occurring in his own practice.

Adenomyoma of the rectovaginal septum is a tumor described only comparatively recently, all the

Fig. 1.—Radiogram after barium clysma; shows long sigmoid colon, but no growth.

cases being reported since 1909. This is a neoplasm developing in the triangular space between the cervix uteri in front, the rectum behind, and the peritoneum above. As the tumor grows it may extend upward, gluing the cervix to the rectum, backward into the rectum or laterally into the broad ligaments. An arbitrary classification of these tumors has been made, depending upon the direction of the extension of the growth. Naturally a tumor that belongs to one class this year, may, by its growth, at a later date belong to another class.

My interest in adenomyomata is due to the following case which appears to be unique:

Mrs. V., born in France, aged 37 years, married, and the mother of two healthy children, was referred to me in September, 1916, because of rectal hemorrhage and pain. Six years before she had "pulmonary tuberculosis which was cured in France." Menses are painful and the flow is gradually ceasing, no leucorrhea. Prior to three years ago she was always constipated. Then she had an attack of diarrhea lasting five months. Thereafter intermittent attacks occurred and during the past year stools have averaged 10 to 12 daily, containing fresh blood and mucus. During the past three years patient has had pain over the lower sacrum, aggravated at the menstrual period and with the diarrhea.

Physical examination showed a rather pale but well nourished woman of 5 ft. 5 in., weighing 142 lb., which is her average. Hemoglobin 85 per cent. Wassermann of the blood was negative. Uranalysis was normal. Chest and abdomen were negative. Rectal examination: Three and one-half inches up on the anterior rectal wall, just above the cervix uteri, the finger feels a hard, fixed, fairly tender mass, the limits of which cannot be clearly defined, and on which the overlying mucosa is not movable. The proctoscope shows a superficial ulceration the size of a quarter-dollar at the rectosigmoidal juncture which is red and clean and bleeds freely on contact. Elsewhere the rectum and sigmoid were normal. Vaginal examination: Uterus normal in size and position and movable. The lateral fornices were clear, but in the posterior fornix was felt the same hard, tender, slightly movable mass, the size of a guinea hen's egg, as was felt per rectum.

Operation, September 26, 1916: Gas and ether anesthesia. Trendelenburg position. Left rectus incision. The sigmoid flexure was very long, as indicated by the *x*-ray (Fig. 1), and contained an excess of yellow fat in its mesentery. No growths were felt in the liver or other abdominal organs. The tumor was located in the anterior wall of the sigmoid just above its juncture with the rectum and extended downward 2 in. onto the rectum, cervix uteri, and posterior vaginal wall. Lower third of sigmoid was mobilized, including a small portion of the posterior wall of the uterus and its cervix, and the superior hemorrhoidal artery was ligated. Then the abdominal wound was closed and in the lithotomy position the operation was completed by a typical Genu-Tuttle extirpation of the rectum, including the posterior vaginal fornix, 1½ x 2 in., which was involved in the tumor. The sphincter ani was preserved and the sigmoid sewed to the perianal skin, thus forming the new rectum. About 4 oz. of blood was lost, but shock was marked at the end of the operation. However, the patient responded promptly to one intravenous infusion. Bowels acted on the third day. Union of sigmoid and skin was primary except at one small space of ½ in. which soon granulated. Patient left the hospital three and one-half weeks after operation and is now well, having normal anal sensibility for bowel actions which now occur once or twice daily with normal control. Her weight is 146 lb., a gain of 4 lb. since operation. Vaginal and rectal examinations show no abnormalities.

The points of interest in this and similar tumors in this location center in their origin, diagnosis, prognosis, and method of treatment.

Origin.—W. J. Mayo[4] states that "As yet there has been no good explanation of the absence of myomas in the voluntary muscle and the frequency of these tumors in the involuntary muscles. The cause is undoubtedly connected with the primitive power of contraction of smooth muscle fibers and their ability to hypertrophy quickly in response to demand. In this connection it is well to remember that the round, broad, ovarian and uterosacral lig-

Fig. 2.—Photomicrograph of adenomyoma of the rectum; mucosa not ulcerated.

aments contain smooth muscle derived from the uterine wall and that myomas and adenomyomas (Cullen) may occur in these locations." The origin of adenomyomas is not always clear. Cullen and Jessup, on the basis of histological study, con-

clude that in most cases they originate from the uterine mucosa which with the smooth muscle has an inherent tendency to invade adjacent structures. Jessup[6] says, "The epithelial cells lining the glands are cylindrical and cilia can be demonstrated on the surface of some." Such findings would be conclusive proof of the source of the particular tumor in question. Lockyer[6] suggests that these tumors arise from the remains of Wolffian ducts. Stevens[7] says that some cases reveal no connection with the uterine mucosa and "consequently their origin cannot be ascertained." Some cases at least seem to be true neoplasms, developing from embryonic rests persisting from the fusion of Müller's ducts.

In my own case the tumor clinically was essentially an intestinal growth. No other tumor like it has been described so far as I can learn. Grossly, the tumor was incorporated in the intestinal wall and the main direction of growth was toward the bowel lumen, where it caused a pressure necrosis of the mucosa over an area the size of a quarter. After careful study of the gross tumor and microscopic sections (Figs. 2 and 3), Dr. James Ewing reports: "Your intestinal tumor is an adenomyoma

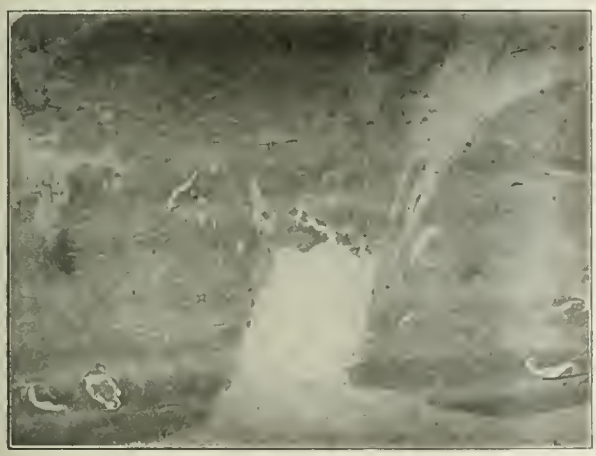

Fig. 3.—Photomicrograph of adenomyoma of the rectum; mucosa ulcerated.

and its close incorporation in the muscle coat of the rectum indicates that it belongs originally with the portion of muscle tissue. The most likely origin is from superfluous material derived from that portion of the lower gut which continues on in the embryo to the bladder and allantois, and which normally atrophies. Persistence of a portion of this segment would furnish a source of smooth muscle and intestinal epithelium. I do not think the tumor is of Müllerian origin."

Symptoms.—Naturally this variety of tumor might be latent for years. Later, varying with the stage of development and location of the growth, the symptoms would be: (*a*) Obstructive, when the bowel lumen is encroached upon. (*b*) Dysenteric—frequent stools containing blood—when pressure necrosis of the mucosa has occurred, or (*c*) Neuralgic—when sensitive nerves are compressed—evidenced especially by sacral and rectal pain.

Diagnosis.—Unless the examiner were on his guard, as a result of previous experience, it is doubtful if he would even consider adenomyoma. Certain tumors, notably adenocarcinoma and polyps, impart a characteristic feel to the examining finger. To recognize them promptly, however, one must have felt them many times. Likewise rectal adenomyoma has a peculiar feel which the examiner would not be apt to forget. Both of the cases of adenomyoma of the rectovaginal septum reported by Jessup had been pronounced inoperable "on account of the apparent involvement of the rectum by a malignant growth."

If sarcoma occurred in the rectum one would think of it. The so-called "rectal shelf" described by Bloomer and English writers, an implantation of a carcinoma in Douglas' sac, would be another possibility; to be recognized, however, by discovery of the primary growth elsewhere in the abdomen. In my case the sensation was that of an infiltrating malignant growth.

Prognosis.—Histologically adenomyoma is a benign tumor. Yet clinically, as in my case, it may become malignant from the severe symptoms—pain, bleeding, etc.—to which its extension gives rise. Moreover, actual malignant transformation may occur.

Treatment.—Surgical removal is the only curative therapy. The practical question is how it may be best accomplished. In view of the progressive nature of these growths, the longer their removal is postponed the more difficult it becomes. Early removal would, therefore, seem to be the procedure indicated, both to subject the patient to the least surgical risk and as a prophylaxis against malignancy. Of tumors of the colon, those at the recto-sigmoidal juncture are, from the standpoint of technique, most difficult for successful removal. Unless contraindicated by old age, marked debility or obesity, I believe that approach should always be made through the abdomen. Thus only can the extent of the growth be defined and metastases be recognized. In some cases the operation can be completed through the abdominal incision. If, however, a considerable portion of bowel must be sacrificed, the dangers of infection, peritonitis and fecal fistula are very grave. In such instances it is far safer, if the sigmoid is sufficiently long, to mobilize the portion of bowel containing the tumor, close the abdomen and complete the operation by the perineal route, doing a Genu-Tuttle or similar extirpation of the rectum, preserving the sphincter ani and forming a new rectum from the sigmoid, which is sewed to the anal margin.

As the number of cases of adenomyoma of the rectovaginal septum reported in recent years is comparatively large, and now my own case of adenomyoma of the rectum proper, it is a fair inference that many others have been missed or wrongly diagnosed either because the diagnosis has been made upon the gross appearance or the tumor has not been submitted to a careful and thorough microscopical examination, as Cullen found in a review of some of his specimens. We owe it to our patients to have every excised neoplasm thoroughly studied by a competent pathologist as the precise nature of the growth is full of significance for the ultimate prognosis.

THE NON-SPECIFIC PROTEIN TREATMENT OF PSORIASIS.

A PRELIMINARY COMMUNICATION.

By ELEANOR VAN NESS VAN ALSTYNE, PH.D., M.D.

NEW YORK.

The treatment of psoriasis as at present practised in the dermatological clinics gives striking evidence of the aphorism "Once a psoriatic, always a psoriatic," a conclusion which has become in fact almost an axiom in the practice of medicine. The conflicting character of the opinions regarding the value of a variety of therapeutic measures gives striking testimony to their limitations. Low protein diet, the administration of arsenic and thyroid extract are measures constitutional in character that have much testimony in their support, but have not proven universally effective. The application of chrysarobin and mercurial ointment is a favorite and widely accepted method of dealing with the skin lesions but can scarcely be considered as more than symptomatic treatment unless one accepts, as some do, an external causative agent in the disease. Nevertheless, they have much experience back of them, and, regardless of their inconvenience to the patient, have been found of service in relieving the disfiguring and annoying lesions of the disease. The

Fig. 1.—Case I, one week after beginning treatment.

proper treatment of psoriasis demands, however, a regime that remedies the fundamental fault, for it has long been recognized that the successful treatment of an attack offers little promise toward prevention in the future. It is the purpose of this paper to describe a therapeutic measure which has been applied successfully to a number of cases of well-developed psoriasis, and which seems to bear a logical relationship to its pathogenesis.

In a recent communication[1] Schamberg and Raiziss have reiterated and corroborated the conclusions voiced in two former papers;[2] namely, that the nitrogenous metabolism in psoriasis presents considerable deviation from that of normal individuals. They find in practically all cases studied a marked tendency to store up nitrogen in the body, while in certain severe cases they found the nitrogen elimination in the urine was depressed to the lowest level ever recorded either in normal or pathological conditions. They are warm advocates of the low protein diet. Even on an unusually low protein intake the psoriasis patient shows a capacity to retain nitrogen, and in comparison to eczema this nitrogen retention capacity is strikingly more marked in psoriasis. This retention is especially well marked during and after the outbreak of the eruption. One of the eczema patients showed a marked nitrogen retention somewhat similar to psoriasis, and it was in this case that low protein diet exerted a beneficial effect which, as they state, is gradual and progressive. Examination of the blood in both eczema and psoriasis showed no increase in the non-protein nitrogen, which fact speaks for a true tissue retention due to disturbed cellular metabolism and not to a renal disturbance.

Fig. 2.—Case 1, six weeks after beginning treatment.

These experiments of Schamberg and his coworkers are of great interest and fundamental importance as they point to a metabolic error that must be corrected by a constitutional agent or influence that will stimulate the body cells to deal normally with the protein intake. Low protein diet may be of service in relieving the condition as it brings to the functionally damaged cells a smaller amount of material that they are incapable of metabolizing in normal fashion and so less imperfectly metabolized nitrogen can accumulate in the organism. In somewhat the same manner the diabetic organism may be protected from partially oxydized carbohydrate

by reducing to a low figure the carbohydrate in the food. The normal organism rapidly adjusts itself to the nitrogen level in the food supply and continues in equilibrium while the psoriasis patient, as shown by Schamberg, stores nitrogen even on

FIG. 3.—Case 1, one week after beginning treatment.

a low nitrogen intake. Chittenden and his coworkers have shown that nitrogen equilibrium may be maintained at a lower level than was used by Schamberg, so there can scarcely be question that the psoriasis patient has a faulty mechanism for dealing with protein, and this is not a difficulty in absorbing the nitrogen, but is apparently a fault of cellular metabolism. The favorable results obtained by Walker in giving psoriasis patients thyroid extract may be due to the well-known stimulation to metabolism which this gland extract produces.

The therapeutic method described in this paper approaches the matter from another angle. It has been demonstrated, by so many investigators, that particular reference is unnecessary, that parenteral injection of a foreign protein stimulates the development of enzymes capable of splitting the particular antigen much as the digestive enzymes pepsin and trypsin do. There is, furthermore, much evidence that an antigen stimulates antibodies not in all respects specific. Certain of the methods used in experimental work show that some of the reactions produced by foreign protein injection are specific to a high degree, notably the anaphylactic reaction; others seem to be class reactions, and Hektoen has shown that the antibodies developed from bacterial proteins have class reactions. Clinical observations afford some substantiation of such ideas. It seemed possible to stimulate the capacity of the organism to deal with protein more effectively by giving subcutaneously injections of a comparatively non-toxic foreign protein. Such a method has been followed in the treatment of four cases of psoriasis, and while it is not possible to give as yet figures to show whether such treatment corrects the nitrogen retention, the clinical results are so striking as to warrant their publication.

The protein selected for this purpose was prepared from millet and alfalfa seed by the method recently described in this journal.[2] The method in question is a simple one: "Fifty grams of the seed meal are placed in a flask with a reflux condenser; 1000 c.c. of distilled water and 40 c.c. of 10 per cent. hydrochloric acid are added. The mixture is boiled for three hours and the coarser particles strained out through gauze. The filtrate is concentrated to 200 c.c. approximately and the excess of acid neutralized with 10 per cent. solution of sodium hydroxide. It will be found that an abundant precipitate of acid albumin forms when the extract is neutral to litmus. It is best to add sufficient sodium hydroxide to get a very faint alkaline reaction to litmus. A portion of the first precipitate formed will redissolve under these circumstances. The faintly alkaline solution is filtered and the filtrate concentrated to such a point that its nitrogen content is 0.3 per cent. as measured by a Kjeldahl determination. The concentration needed for this purpose varies somewhat in each case, but the final bulk of the standardized protein solution from this amount of material is

FIG. 4.—Case I, six weeks after beginning treatment.

about 100 c.c. If the reaction is very faintly alkaline the solution may readily be sterilized by boiling. The solution contains alkaline albumin, proteoses, and a small quantity of peptone. It is a most excellent culture medium for a variety of

organisms and ought to find extensive use in bacteriological laboratories for this purpose, but for therapeutic use the only safe way to preserve it is to seal the solution in small glass ampoules which are then sterilized by the discontinuous method."

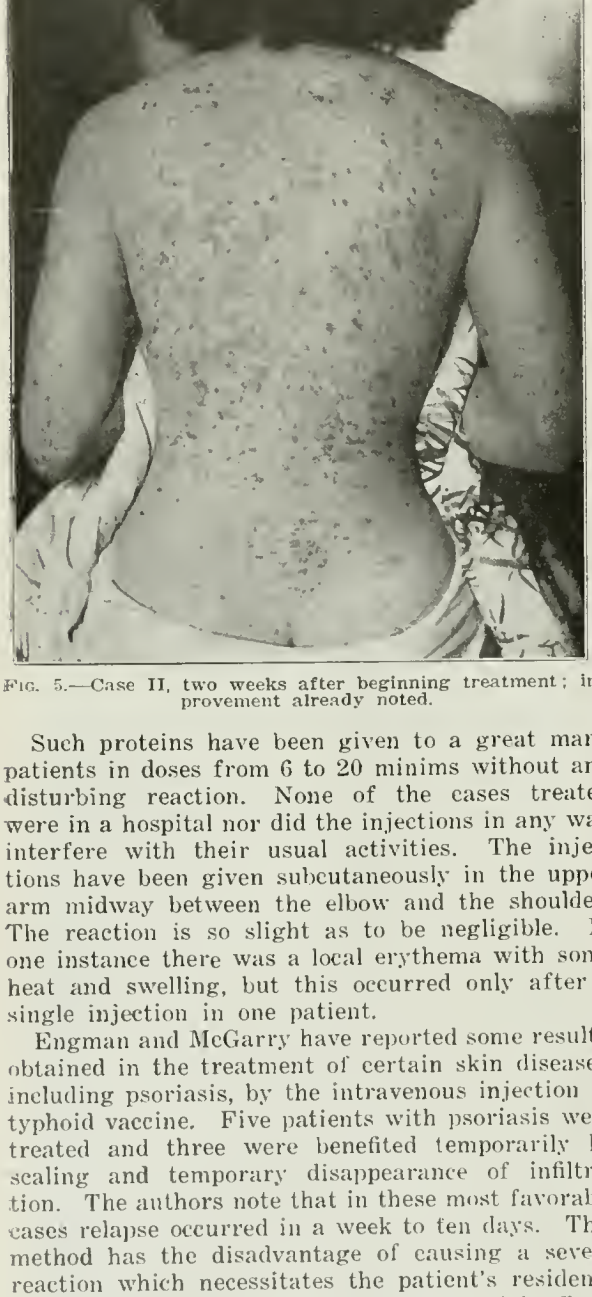

Fig. 5.—Case II, two weeks after beginning treatment; improvement already noted.

Such proteins have been given to a great many patients in doses from 6 to 20 minims without any disturbing reaction. None of the cases treated were in a hospital nor did the injections in any way interfere with their usual activities. The injections have been given subcutaneously in the upper arm midway between the elbow and the shoulder. The reaction is so slight as to be negligible. In one instance there was a local erythema with some heat and swelling, but this occurred only after a single injection in one patient.

Engman and McGarry have reported some results obtained in the treatment of certain skin diseases, including psoriasis, by the intravenous injection of typhoid vaccine. Five patients with psoriasis were treated and three were benefited temporarily by scaling and temporary disappearance of infiltration. The authors note that in these most favorable cases relapse occurred in a week to ten days. This method has the disadvantage of causing a severe reaction which necessitates the patient's residence in a hospital, and while certain beneficial effects were observed they did not compare in extent or character with those reported in this paper. The results herewith presented demonstrate that it is not necessary to use a highly toxic bacterial protein which seriously disturbs or inconveniences the patient, and it can hardly be argued that a long-continued intoxication with so virulent a poison as the typhoid organism is to be preferred to the comparatively non-toxic action of the proteins described.

Four patients have been treated by this method by the writer, and the details will be summarized.

Case I.—Mrs. S., age 45 years. First attack eighteen years ago. Recurrent attacks to date. Skin never free of lesions. Present exacerbation began in December, 1916. First seen March 12, 1917, when patient presented a condition of generalized psoriasis. Patient was in fair general condition with normal blood and urine, although somewhat over weight. Previous treatment had consisted of meat free diet and the application of chrysarobin and ammoniated mercury ointment.

Treatment began March 12 with a subcutaneous injection of 4 minims of the protein solution. Dosage was gradually increased up to 12 minims. For ten weeks injections were given three times weekly and for six weeks one injection weekly. The patient was on a general mixed diet during the treatment and was given a mixture of rhubarb and soda to keep the bowels open. The photographs show the condition of back and abdomen on March 17, five days after the first injection, and on April 24, six weeks after beginning injections. The improvement was a gradual one and was first noted in a fading of the inflammatory reaction about the base of the larger patches. The patient is now (July 23), four and one half months since treatment began, in fine condition.

This patient had been a psoriatic for many years with extensive large lesions scattered over the whole surface of the body and especially well marked on elbows, knees, and scalp.

Case II.—Miss M., age 19 years. First attacked in September, 1916, was a generalized psoriasis treated with chrysarobin ointment with only partial relief. March 1, 1917, marked exacerbation of condition, which was not favorably influenced by chrysarobin. Patient first seen by the writer April 10, 1917; when a condition of generalized psoriasis was presented, the thighs, legs, and scalp being also extensively involved. Treatment began April 10, with injection of 4 minims and continued triweekly until May 25, the dose being gradually increased to 12 minims. From May 25 to July 13 one injection was given weekly. Patient was given mixture of rhubarb and soda to keep bowels open.

Fig. 6.—Case II, nine weeks after beginning treatment.

but continued on a general mixed diet. It is worthy of note that this patient is very fond of meat and always ate freely of it twice daily and frequently three times daily throughout the treatment. The photographs show the progress in improvement observed on this patient, but it should be noted that the first photograph was taken two weeks after beginning treatment at a time when improvement had already begun. Again the first indication of betterment was seen in a diminution of the erythema about the scaly patches followed by falling of the scales.

This patient is now (July 20) a pink cheeked, clear skinned young woman, who has gained nineteen pounds during the treatment and is practically entirely free from psoriasis even in the scalp. The last lesions shown in the photograph of July 13 have entirely cleaned up.

Two other patients, one a young man of 27 years, with generalized psoriasis of five years standing, and the second a young girl 12 years of age with

FIG. 7.—Case II, after three months of treatment.

a psoriasis extending over five years and an acute exacerbation just beginning, have been treated in the same way with results similar in character to those already described. Since photographs of these patients are not available at present, their case histories are not given in detail.

Observations and Summary.—1. The subcutaneous injection of proteins prepared from millet and alfalfa seed has been found to produce a markedly beneficial effect upon the general condition and specific lesions in four cases of psoriasis. This is one hundred per cent. of the treated cases.

2. The injections have produced no disturbing reaction, either local or general, and have in no way interfered with the usual activities of the patient.

3. The improvement in the skin lesions begins in from two to five weeks after the injections are begun at a time when the larger injections have been reached.

4. The skin lesions have improved without modifying the diet and without the use of local applications.

5. It is not possible to make any predictions as to the permanency of relief afforded by this method. It seems possible, however, that when a good condition is once established, an occasional injection may be serviceable in preventing a new exacerbation.

6. The injections in no way interfere with the dietary or other forms of treatment that have been used in the past with reported good results. Possibly in stubborn cases a combination of these measures with protein injections may produce more prompt results.

The writer expresses her thanks to Drs. Norton and Bertine for referring the patients pictured in this article.

EPIDERMOID CARCINOMA OF A LARGE BRONCHUS WITH CAVITY FORMATION AND METASTASIS IN THE RADIUS.

BY ERNEST SCOTT, M.D.,
AND
J. W. LEIST, M.D
COLUMBUS, OHIO.
FROM THE LABORATORY OF PATHOLOGY OF THE OHIO STATE UNIVERSITY.

THE fact that since the recent report of four cases of primary carcinoma of the lung from this laboratory, Lambert has reported a series of four cases and in a personal communication mentions four others, and that we have chanced upon an additional case, would add emphasis to the statement that this condition is more frequent than statistics would indicate. Our experience would tend to prove that one of the main reasons for the lack of such cases in the literature is their evident confusion with the more chronic types of pulmonary tuberculosis. In each of the four cases previously reported by us, a diagnosis of tuberculosis had been made, and in the present case such diagnosis was held in abeyance only by the fact that there was an apparently primary tumor of the right radius. Ash has also called attention to such error following his experience in a hospital for advanced tuberculosis.

A thorough investigation of primary carcinomata of the lung tends to show that in the majority of cases such growths take their origin in the mucosa of the larger bronchi. Passler is quoted by Weller as stating that 87 per cent of all primary carcinomas of the lung are of bronchial origin, and

Weller, after imposing rather rigid requirements, cites 89 cases obtained from the literature in addition to the case that he reports personally. Scott and Forman, after the careful examination of many sections, report four cases fulfilling all of the standards set by Weller.

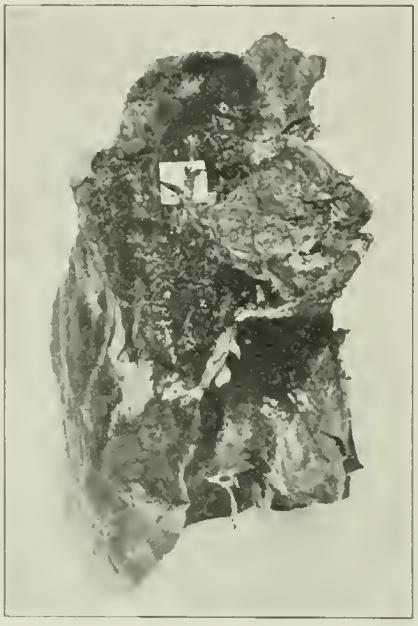

Fig. 1—Showing the cavity of the upper lobe with the stumps of bronchial tubes.

Weller, in discussing the histopathology of 57 of the cases cited by him, shows that 25 were epidermoid in type, 18 were composed of cylindrical cells, 10 of polymorphous cells, and other cases are described as round-celled, gland-celled, and cuboidal-celled. The portion of the tumor from which the sections for microscopic examination are taken may account for this variety of cell types for, as is stated elsewhere in this discussion, the cell structure of these tumors varies greatly in different portions, and as Weller remarks, "Probably most of the cases in the last four of the above groups might have been placed in one or the other of the first two." These statistics are borne out by those of Kurt Wolf, who states that fully 50 per cent of all bronchial carcinomas are of the epidermoid type.

The origin of the squamous epithelium composing these growths has created much discussion, and in his "Lehre von der Krebskrankheit" Jacob Wolff cites several theories advanced by authors who have investigated the subject. Wolf, Griffini, Watsuji, believe that the chronic inflammatory conditions accompanying tuberculosis play a very important role in producing metaplasia of the cylindrical cells of the bronchus into cells of the squamous type. Kurt Wolf offers a further suggestion that the irritation resulting from the rupture of a softened, pigmented bronchial node, which is apt to be tuberculous, into the branchus, may be a cause of the frequent development of the epidermoid cells in this locality. Silgert, Reiche, Passler and Ernst hold that such occurrences of squamous cells are due to embryonal rests or inclusions. While Paul Eicholtz explains their presence by the growth of the cylindrical cells whereby through mutual pressure they become flattened. Haythorn has demonstrated numerous metaplastic areas of this type in the anthracotic lung of a coal miner who died of pneumonia. Irritation, therefore, has been considered an important factor in the etiology of such metaplasia. The fact that the great majority of these epidermoid carcinomas occur in males leads to the opinion that occupation and habits of life which subject the individual to irritating vapors and fumes may play some part as a causative agent. The fact that the case of epidermoid carcinoma in our previous series occurred in a chemist who had spent years in a smelting works and was an excessive user of strong tobacco added to our belief in this suggestion. The present case, however, gives nothing to substantiate such a view, for the patient had always been employed as a building carpenter spending much of his time in the open air and there is no history of unusual irritation of any kind.

History: Patient, J. W., age 67, carpenter, nativity United States, admitted to Protestant Hospital, November 5, 1916, complaining of aching pain in right side of chest, cough, and a "feverish feeling." Mother died of pneumonia at the age of 80. Two brothers died of tuberculosis. Otherwise the history is unimportant. The cough, which was the chief symptom at the time of admission, was said by the patient to be of recent origin. A daughter, however, states that he had had a mild cough for a period of fifteen years, and that there had been a marked increase in its severity three months prior to his entrance into the hospital.

In July, 1915, the patient suffered a fracture of the right forearm near the wrist. This injury healed readily, but the part always remained weak. In May, 1916, he received a rather severe bruise to the upper part of the same forearm, and soon after this he noted a slight swelling of this portion of the arm. *X*-ray examination showed a distinct rarefaction of the upper portion of the radius and a diagnosis of osteomyelitis was made. The part continued to increase in size, however, until the patient was forced to seek medical aid and entered Grant Hospital, October 2, 1916. A second *x*-ray examination made at this time lead to a diagnosis of sarcoma of the radius and an amputation of the arm at the middle third of the humerus was made.

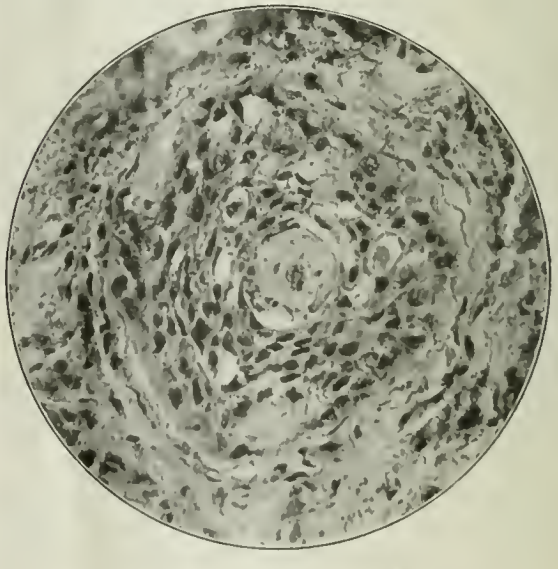

Fig. 2—A mass of epithelial cells, showing keratinization of its center.

The patient states that soon after the operation he "caught cold" and began to cough. He had no chill, but noted the development of an aching pain in the lower portion of the right side of his chest. After leaving the hospital he was about for only a few days when he was forced to return to bed because of weakness.

His cough had been persistent and was productive of large amounts of thick chocolate colored sputum. Repeated microscopical examination of the sputum failed to reveal tubercle bacilli, but showed numerous streptococci with pus cells and erythocytes. No fragments of lung or tumor tissue were encountered.

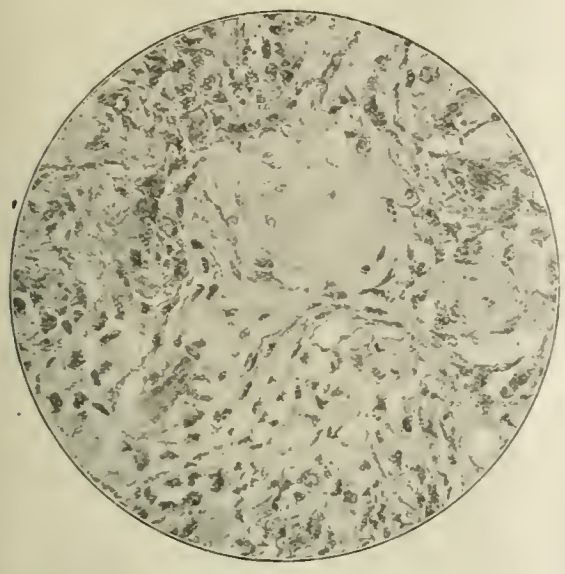

Fig. 3—A higher magnification of keratinized epithelial cells.

At the time of entrance into the Protestant Hospital, the patient presented the following physical findings:

Male, white, markedly emaciated and pale. The right arm amputated in middle third of humerus. The amputation stump is practically healed, but still shows a dark scab at the center of the wound. The pupils are sluggish, the teeth missing, the tongue thickly coated and tremulous, the heart sounds feeble. Cracked pot resonance and amphoric breath sounds are heard over the entire right upper lobe of the lung anteriorly and over the right supra spinus fossa. Tenderness on percussion is elicited over the second and third right interspaces anteriorly. Dullness and bronchial breathing are present over the entire right lower lobe. There are fine moist rales over both lungs and coarse moist rales over the right upper lobe. There is a distinct friction rub over the lower lobe of the right side. Four days after his entrance he suffered from a moderate pulmonary hemorrhage.

The blood pressure is systolic 95; diastolic 50. The blood count, hemoglobin 75 per cent., red cells 4,792,000, leucocytes 12,000, polynuclear 67 per cent., small lymphocytes 14.0 per cent., large lymphoctyes 8 per cent., large mononuclear 0.5 per cent., transitional 8.0 per cent., eosinophile 2 per cent., mast cells 0.5 per cent. The urine showed a trace of albumin, a few granular and hyaline casts, and a moderate number of leucocytes. The clinical diagnosis is bronchopneumonia with abscess, and possible metastatic sarcoma of the right lung.

The classical symptoms of primary carcinoma of the lung are cough, dyspnea, dull pain, hemoptysis, and cachexia. Adler in his monograph states that pain is the most common and constant as well as the earliest symptom of this disease. In the case under discussion these symptoms were more or less irregular in their manifestations. The cough which was rather pronounced in the later stages of the disease was indefinite during its earlier course. Dyspnea, which was a visible symptom during the last stages of the illness, was not present earlier and was never complained of by the patient. Pain in the chest was complained of only late in the disease and was then located in the lower portion of the thorax. Hemoptysis was not present and the cachexia was not marked until the disease was well advanced.

These somewhat irregular symptoms combined with the rather typical physical signs of extensive cavity formation and the presence of a bronchopneumonia, did not apparently warrant a diagnosis of carcinoma of the lung. In fact, tumor of the lung would have been entirely discarded had it not been for the supposed primary sarcoma of the radius. Weller has drawn attention to the fact that in cases of primary cancer of the lung with metastasis the metastatic growth may so dominate the clinical picture as to lead one astray in diagnosis.

Autopsy Abstract: Anatomical Diagnosis. Malignant tumor involving the upper lobe of the right lung with attachment to the inner surface of the first rib of the right side; metastatic nodules in both kidneys and both adrenals; necrosis and cavity formation in the upper lobe of the right lung; occlusion of the right bronchus by a mass of cellular and necrotic material; pleural adhesions over both lungs especially marked about the upper lobe of the right lung; increase in the pericardial fluid; bronchial pneumonia in the lower right lobe; fibrosis of the aortic valves; diffuse atheroma of the aorta; absence of the right arm from amputation.

Histological Diagnosis: Epidermoid carcinoma of the right bronchus.

Thoracic Cavity: Upon the removal of the sternum a firm mass of adhesions is encountered at the upper anterior portion of the right lung. In severing the tissues from the sternum, a cavity in the upper lobe of the right lung is exposed. This cavity measures 8 x 11 cm. and contains in its lower portion a mass of necrotic tissue which is attached by a fibrous strand to the anterior wall of the cavity. The inner walls of the cavity are rather well defined and are coated with a small quantity of necrotic material. The upper portion of the wall is firmly adherent to the inner surface of the upper two ribs, and upon separation it is found that there is a mass of pale firm tissue attached to the inner surface of the upper rib. This mass of tissue measures 6 x 3.5 x 1.5 cm. In the wall of the cavity there are several areas of thickening which seem to be composed of the same kind of tissue as that seen on the inner surface of the rib. The first of these thickened areas measure 3 x 4 cm. in diameter. The second measures 2 x 3 cm., and the third 1 x 1.5 cm. These areas are in the thickened pleura and bear a very intimate relation to the necrotic material lining the wall of the cavity.

The right pleural cavity contains 300 c.c. of turbid fluid and exhibits many adhesions over the middle and lower lobes of the lung in addition to those described for the upper lobe. There are also adhesions over most of the pleural surface of the left lung.

Lungs: Upon removal of the right lung, it is found that the cavity above mentioned occupies almost the entire upper lobe and that its inner wall is ragged and dark in color. The lower lobe of this lung is somewhat consolidated, and on cut section the surface is mottled, showing small grayish areas about the bronchial tubes. In the lower portion of the lobe, these areas fuse, and the condition resembles that of lobar pneumonia. The

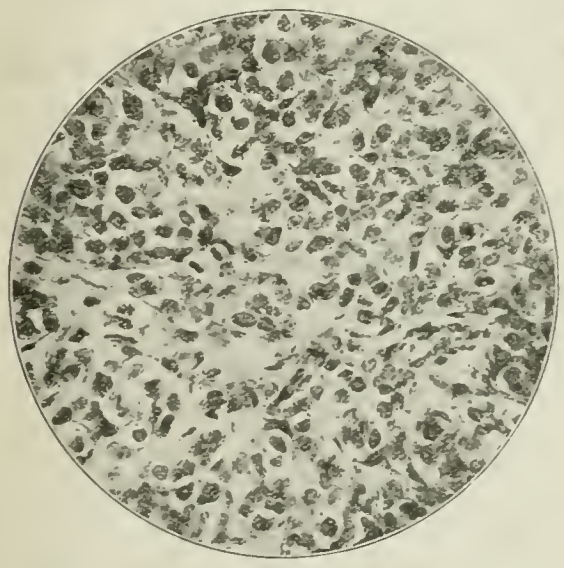

Fig. 4—Cell type seen in the metastatic nodule in the radius.

middle lobe of this lung presents an area of consolidation on its anterior margin which is chiefly due to edema.

The bronchial tube leading to this lung is almost entirely occluded by a mass of soft necrotic material similar to that seen within the cavity. The bronchial lymph glands at the root of this lung are greatly enlarged, one mass measuring 4 x 2.5 cm. in diameter. Their color is dark with grayish areas intermingled.

The left lung is large, its firmness is somewhat increased, and upon section a large quantity of frothy blood-tinged fluid escapes, indicating a rather general edema of this lung. The bronchial lymph nodes are not remarkable. The bronchial tubes contain a moderate amount of mucopurulent material. The mucous membrane is congested.

Histopathology: Sections taken from the thickened areas in the cavity wall and from the mass attached to the first rib show a distinct grouping of the cells, these groups are separated and surrounded by well developed bands of fibrous tissue. The cells are large, irregularly round, and have large deeply staining nuclei. In some of the cell masses a concentric arrangement can be seen and at their centers keratinization is well marked. Thus leaving, no doubt, as to their epithelial origin. In some of the sections, however, the cells have not fully differentiated and are seen as small, irregular, dark staining, spheroidal cells and, as were described by Scott and Forman, "they appear when taken by themselves not unlike those from certain sarcomas." The cell type found in the growth in the radius, correspond to those last described, being small, irregular cells without definite grouping and closely resembling in form and staining reaction the undifferentiated cells of sarcoma. In this connection Ewing's observation that "it is becoming more and more apparent that so-called sarcomas of the organs are in reality spindle-celled carcinomas" is of special interest. For in three of our previously reported cases the cells more remote from the bronchial tubes lost their differentiation almost completely and were seen as small round or spindle cells with dark staining nuclei and a scant indefinite protoplasm.

Discussion—The features of special interest in the present case are the extensive cavity formation and the unusual metastasis in the radius. It is usually stated that metastasis to the bones occurs most frequently in cases of carcinoma of the thyroid, mammary gland and prostate. Wolff quotes E. Fränkel as stating that 20 per cent. of all carcinomas of the prostate gland give rise to metastatic growths in the bones. Rodman believes that metastasis in the bones occurs very frequently following carcinoma of the breast, and cites the work of Herbert Snow showing that 9 of 12 unsuspected cases examined gave microscopic evidence of such metastasis. Hassler cited by Crotti reports 140 cases of thyroid carcinoma, 34, or 24.3 per cent., of which gave metastasis in bones.

Of the 498 cases of primary carcinoma of the lung reported at this time, exclusive of the case under discussion, 62, or 14 per cent, show metastasis in the bones, thus indicating that carcinoma of the lung stands well up in the list of those giving metastasis in the bones.

Fifty-eight of the cases in Adler's series are recorded as giving metastasis in the bones. In some the metastasis was multiple, in others single. In this series twenty-two of the secondary growths occurred in the sternum and ribs, twelve in the vertebræ, ten in the skull, three in the femur; the right humerus, the ilium, the shoulder joint, the finger, the clavicle and the "long bones" are each recorded as being involved once. Under the heading of "Metastasis to the Bones," five cases are recorded. Aside from these Wiczkowski reports a single instance of metastasis occurring in the ribs and vertebræ in his series of thirteen cases and Weller in his series of nineteen cases, not cited by Adler, reports a case in which secondary growths were found in right femur and in the vertebræ. Gilchrist mentions metastasis as occurring in the ribs in his case, and in one of the cases reported by Lambert metastasis occurred in "various bones (vertebræ and ribs especially)." In the remainder of those cases recorded since 1912, to which access is possible, no mention is made of metastasis to the skeletal system. A review of these recorded cases, therefore, indicates that metastasis to the bones of the arm is rare, the only ones mentioned being those of Adler's series in which a single case (Japa) showed metastasis in the right humerus and one other (Hinterstosser) in the third phalanx of the right ring finger.

The formation of cavities accompanying primary carcinoma of the lung takes place in a considerably lesser number of cases than does the metastasis to the bony structures, it being recorded in only thirty-four of Adler's series and in none of those since reported. In six of the cases described the cavities were small and multiple, in four others the tumor was complicated by tuberculosis, so that it is somewhat uncertain whether the cavity was due to the carcinoma or to the tuberculous process, thus leaving less than 5 per cent of the cases showing well defined and uncomplicated cavity formation.

Summary—It is becoming more and more apparent that carcinoma of the lung is not of infrequent occurrence. It, therefore, is to be borne in mind more constantly by the diagnostician.

Metastasis to the bones is present in 14 per cent of the reported cases of primary lung carcinoma.

Cavity formation is present less frequently (5 per cent), but is at times a complicating factor in diagnosis.

The microscopical examinations of tissues taken at a distance from the seat of origin or in the metastatic growth is apt to lead to an erroneous diagnosis.

Our sincere thanks are due to Dr. J. F. Baldwin for portions of the history and for the record of the amputation, to Dr. C. F. Bowen and Dr. H. J. Means for the x-ray photographs, and to Dr. E. R. Shilling for the use of microscopic slides from the growth in the radius.

PHYSICAL ATTITUDE AND VITAL EFFICIENCY.

BY SILAS WRIGHT GEIS, PH.D.,
NEW YORK.

THERE is only one way to increase vital efficiency by means of physical attitude, and that is to adopt an attitude that augments the normal, habitual capacity of the lungs; for the air that enters the lungs is the "steam" that generates bodily activity. Other things being equal, the more air a man's lungs can normally utilize during each respiration, the greater will be his physical effectiveness.

How are we to establish this Position of Maximum Vital Efficiency? Here are the directions, as they have been worked out in the writer's experience, during a period of over 15 years.

First—Raise the shoulders, straight upward and slightly backward, until they are perfectly square.

Second—Now draw the body straight upward to the greatest height you can make it attain. Do this by sheer will-power, without consciously using any local muscular force. Then there will be no strain. To put it another way: make yourself as tall as possible; or try to press the top of the head against an imaginary object just above it.

These two movements elongate the chest and maximize the capacity of the lungs in a vertical direction.

Third—In raising the body to its greatest height, it will be found that the backbone straightens out, corrects its tendency to curve outward, and assumes a slight inward curve. Accordingly, our next direction is to accentuate this forward curve of the spine, but only so far as is consistent with maintaining the attitude of extreme tallness above described. These two movements supplement and balance each other. By arching the backbone frontwards (making one's self slightly sway-backed) the capacity of the chest is maximized in a frontward-backward direction.

Fourth—Expand the lower ribs, at the two sides, in a lateral direction. Push them apart (outward) as far as you can by will-power, without consciously using local muscular force. Now, maintain them in this position, except in so far as it may be necessary to let them fall slightly inward during each expiration. In other words, let the sidewise movement of the lower part of the chest be from maximum to medium expansion; instead of being from medium to slight expansion, as is generally the case. This maximizes the capacity of the lungs in a sidewise direction.

For the sake of simplicity, we have described the Attitude of Maximum Vital Efficiency under four separate headings; but as a matter of fact, it is attained by a single impulse. The mind forms a picture of the attitude in its entirety; the will instructs the body to imitate this picture; and repetition of this process establishes the desired attitude as instinctive. This is rendered all the easier because each movement co-operates with the other three: the squaring of the shoulders and the arching of the backbone slightly forward assist in raising the body to its full height; and the maintenance of the body at its full height helps to keep the backbone and shoulders in place; whereas all these movements co-operate to put the lungs in a position where they expand themselves, along their horizontal diameters, with greatest ease.

The distinguishing feature of the attitude herein described is that it augments, to the utmost, all three dimensions of the chest, and maximizes the habitual capacity of the lungs—all without muscular strain. There is no interference with the instinctive process of breathing, but simply a fuller use made thereof. The results of this are soon realized in the shape of better physical welfare and endurance, along with their spiritual counterparts of greater buoyancy and will-power.

Reduced to its lowest terms, for teaching purposes, the Attitude of Maximum Vital Efficiency may be summarized as follows:

"Square your shoulders.

"Make yourself as tall as you can, and slightly sway-backed.

"Keep the lower ribs expanded at the sides."

YALE CLUB.

Medicolegal Notes.

Physical Examination of Suitor for Damages.—The Oklahoma Supreme Court holds that where the plaintiff in an action for damages for personal injuries exhibits a portion of his body to the jury and physicians called by him testify as to the nature and extent of his injuries, and the plaintiff offers to submit to an examination by any physician or board of physicians named by the court other than those in the employ of the defendant and who are shown to have been employed by the defendant, and who are to receive $25 per day for testifying in the case, it is not error for the court to refuse to require the plaintiff to submit to an examination by the physicians employed by the defendant.—Oklahoma Ky. Co. vs. Thomas, 164 Pac. 120.

Necessity to File Certificate to Practise.—The Iowa Supreme Court holds that the requirements of Code, Sections 2576, 2577, 2580, that, before engaging in the practice of medicine a certificate must be obtained and filed by such person attempting to practise medicine in the State are mandatory, and no one can engage in such practice until he has complied with all the statutory requirements. It is held that a physician who had failed to comply with Code Section 2577, requiring him to file a certificate for record in the office of the county recorder, could not maintain an action for the value of services rendered, though his failure was due to no intent to evade the law, but to a misapprehension induced by the clerk of the district court as to the proper office in which to file the certificate.—Lynch vs Kathmann, 163 N. W. 408.

Proof of Degree of Skill.—In an action of damages for alleged malpractice in treating an injury to the plaintiff's wrist, it is held that where doctors of equal skill and learning, being in no way impeached or discredited, disagreed as to the proper manner of treatment for the injury as alleged by the plaintiff and the advisability of an operation not performed by the defendant surgeon, the plaintiff cannot recover, because of failure of proof of negligence, since an award of damages would rest upon mere speculation and conjecture.—Dishman vs. Northern Pac. Beneficial Assn., Washington Supreme Court, 164 Pac. 943.

Military Medicine.

LETTERS FROM AN M. M. R. C.

THE consensus of opinion among the officers of the Medical Reserve Corps is that the regulation uniform is far from satisfactory. The so-called dress uniform is neither very smart nor is it comfortable. The standing collar is inclined to choke and the white collar or stock that is called for in regulations to be worn underneath is hardly ever visible and simply adds its discomfort to the rest. There is a general hope among officers that the style of roll collar adopted by the British officers, will be taken up over here and also the shoulder strap belt. Now that everyone has provided himself with the so-called regulation uniform (a gross misnomer as far as material, shade, and cut go) it would be the American psychological moment to have a new model service uniform called for. This would keep sweat shops and cloth factories running full blast, besides the manufacturers of trimmings and buttons. Nothing can ever be done with the old uniform. They will probably be seen for years to come on drivers of garbage trucks and other followers of lowly and arduous occupations. The regulation flannel shirt is supposed to be worn underneath. Beside the collar or stock, white cuffs are called for. It is not difficult to picture the disorganized and sloppy appearance of an officer if for any reason he removes his blouse. A regular army man is always recognized in civilian clothes. He both looks and feels unnatural. Detached cuffs probably seemed all right to the officers who helped design the present uniform. The subject seems too important to be entrusted to any except experts in what is serviceable, comfortable, and smart in the realm of tailordom. The regulation service cap runs the chauffeur to a very close finish. The service hat of felt is absolutely appropriate and suitable to our country. It is a hybrid between the cowboy headgear and the Mississippi gambler of steamboat fame. Of the entire equipment it is the only part that seems appropriate and satisfies all concerned in the wearing. The puttees that officers wear run through every gamut of the scale of putteedom. Short ones are seen, barely coming to the middle of the calf; long ones, so long that they wrinkle up at the heel of the shoe. The American has taken to his puttees in the same fashion as he does to his shotgun. He never bothers about the length of the stock. A man with short arms will use a gun whose stock is unusually long and *vice versa*, utterly regardless whether it fits. They make it do anyway. Many have never bought puttees before and are not expert in judging the quality of leather and the difference between imitation hog skin and real. After the first rain puttees assume all kinds of bizarre shapes—some disintegrate entirely, leaving so many separate leaves of pasteboard. It is a considerable shock to the ordinary practitioner to find that the price of a good pair of puttees will run at least ten dollars off his roll. He does not see the value as compared to his boots, that he is accustomed to paying five dollars for.

There are some odd duties befalling members of the medical officers' training camps that I have not mentioned. Foremost amongst them I must mention the "fly swatting" assignment of duty. Every day five or six officers are assigned to this occupation. They are presented with the ordinary fly swatter and for fifteen minutes after each meal their duty is to bring death and destruction to the flies in the dining hall. It is not unusual to notice a man who heretofore in public life has been known as a scientist or surgeon, mentally engrossed in the occupation. There is food for considerable in this vision of distinguished age engrossed in such lowly pastime. There has in other ways also been a metamorphosis in the character of the medical officers, past belief. Is it temporary or permanent? I have heard of girls breaking their betrothal engagement to men who have enlisted in the officers' training camps, finding them so completely changed in character at the end of their training course. I have heard of women who have discovered their husbands intolerably gloomy and morose since their return from camp. I have heard one wife say that she did not know her husband as the same man since he had cut off drinking his daily anteprandial cocktail. Will the end of this character change mean a flight of prodigious numbers to the divorce court? Seriously, most men, especially those of over forty years, are changed, both in looks and character. They have felt it and show it much more markedly than the young bloods. The majority of the elders have lost weight and their midgirth is considerably diminished. The expression about the faces is, if anything, more drawn and severe. The roots of their past life have been so completely torn asunder that their eyes look into the future without fear or illusion. The worst has happened and now they are ready for anything.

Another odd duty of camp life is to be made "office orderly." In this position you attach yourself to the headquarters or office of your company and cheerfully perform the duty of office boy to your commander, who may be twenty or thirty years your junior. You run errands and deliver messages, you clean out the office, empty the waste paper basket and a thousand other such little jobs. One wonders occasionally if it was not some hideous mistake or dream that you once were considered a surgeon of some renown. It is no dream as to what you are doing. You are playing the game for all it is worth. You are doing the work of office boy in the best manner that you can possibly do it and meanwhile you forget that you are still paying a competent stenographer and telephone operator in your home office to keep things going. This spirit governs all men in camp who have answered their country's call in the proper spirit.

The criticisms that occasionally crop out from this pen should not be taken as a reflection of an unfavorable angle of the whole. Taking all in all I do not see how the Department of the Surgeon General could have accomplished more than it has done in such a short space of time. There is nothing so perfect that flaws cannot be found in it. Admiring the whole, it is natural for one having the organization very near to heart to try by criticism to find the weak points and make it perfect. Past this it is not the author's intention of going. There is another side to the officers' service in training camp that I have purposely avoided. I could tell of clear starry nights, many men gathered in the company street listening to the words falling from

someone just returned from active surgical service on the firing line—all that he heard and saw with his own eyes—the subdued excitement at the feeling that we too may be there before long—even the locusts humming in the grove, while the midday lecture is on to the circling sea of faces in front, has its side of picturesque romance and poetry—the murmur of distant voices singing—the silence of the night that follows taps, with nothing but the stars above you, twinkling through your open tent. The stars. Yes, God bless them! They remind us what we are doing here and we go to sleep contented.

TRENCH FOOT.

Probably no other condition of modern warfare has brought so much hardship to the soldier and presented so many new sanitary and medical problems as trench life. One of the most troublesome of the affections resulting from these conditions is that known as trench foot. Exposure to low temperature and wet for long periods restricts the circulation, especially of the lower limbs, and this is the most active factor in the causation of this disease. In slight attacks there are anesthesia and edema of the parts; in the severe cases there are cyanosis, gross edema, bleb formation, and even serious organic tissue changes. In the very worst cases there is gangrene, accompanied by all the dangers of infection, by destruction of tissue, and loss of limbs. There is a tendency to a contracture of the foot, usually described as a turning under of the foot. At the beginning of the war, trench foot gave a great deal of trouble and caused much of the disability, but now the perfection of general sanitary methods and the construction of better trenches have helped to diminish the incidence of this condition as well as to reduce disease and disability in general. Moreover, as affects trench foot, the smaller sectors and the greater reserve of men, allowing for more frequent change, have of themselves, without the actual preventive methods instituted, reduced both the severity and the incidence of this condition. Where previously the men had to stay in the trenches for long periods, at present there is a change every few days.

As a general prophylactic measure against trench foot it was found that the wearing of looser boots, perhaps a size too large, was of great help. It would prevent the restriction of the circulation, which is so large a factor in the causation of trench foot. The general circulation of the body can be maintained by warmth and by appropriate movements and exercises. Socks must be changed very frequently, and must especially be kept dry. Torn socks are especially liable to constrict the blood vessels and produce injury to the foot. Foot rags, well paraffined, have been tried, with more or less success, to obviate the difficulty of keeping socks whole. If these foot rags are well applied they are found to be far more comfortable than socks. Puttees must be loosely applied. Boots must be thoroughly greased before being put on. Rubber boots have been extensively used, and are looked upon with favor. Thorough greasing of the feet was tried at the beginning, but was found to be offensive to the men, and consequently not conscientiously carried out. The newest, and apparently the most successful, method of preventing trench foot is by means of the so-called "trench-foot washhouses." Immediately before returning to the trenches the men go to these washhouses for treatment. Here they have their feet soaked and washed in warm water and with a special soap composed of soft potash soap 1,000 parts, powdered camphor 25 parts, and borate of soda 100 parts. The feet are then carefully dried, and treated by the regimental surgeon or chiropodist, and finally dusted with a mixture of powdered camphor, talc, and borate of soda. In the trenches the soldiers must be served with hot food in order to maintain warmth and keep up the general circulation.

No amount of attention to the feet of the soldier can be too painstaking as regards their cleanliness, shoeing, and physical condition. To escape disability as the result of actual war violence and to receive it as the result of preventable sanitary conditions, would be indefensible. The pedicuring of the feet is vastly more important than the manicuring of the hands, especially in the case of the soldier. When properly trained and educated to his calling, the experienced chiropodist is a most useful member of the military forces.

A GERMAN VIEW OF TRENCH LEG.

In addition to trench foot and trench hand surgeons have described a so-called trench shin, which manifests itself by pains in the tibia. Quite a literature has grown up about this painful condition in British, French, and Italian journals, and it is claimed that a considerable recent German literature already exists on the subject. According to Peláez this condition is described in full by Sittmann in the *Munchener medizinische Wochenschrift*, No. 32, 1917. The pains which, as a rule, are preceded by malaise, headache, rigors, fever, and lassitude, are most commonly felt on the inner aspect. Absent during the day, they tend to appear in the evening and by night have become unendurable. Warmth aggravates while cold alleviates the suffering which is entirely beyond the control of salicylic acid and aspirin. As a rule, there is no sensitiveness of the bone on handling, but the muscles of the calf and sole are tender to pressure and special tender points may be isolated.

A systematic investigation brings out numerous anomalous symptoms which are not readily coordinated. Active motion does not seem to be inhibited, but upon passive motion the muscles are tense. The sensitiveness of the latter may be reduced at times by use. There is no evidence of motor excitability. In certain cases or at certain times the muscles are hypotonic, and the calf may be relaxed and flabby when the legs are crossed and when the patient lies supine. The calf may even be so flaccid as to suggest a suspended bag. In other cases and especially when the disease is incipient the calf may be swollen, hard, hyperalgesic to pressure and after active movements, especially when made against resistance. In such cases the muscles have a more than normal tension, much as in the myotonus of Thomsen's disease. As a rule this condition wears slowly away.

Disturbances of sensation in the skin are trivial. The patellar and plantar reflexes are, as a rule, exaggerated.

Despite the complexity of the picture the cause is simple—immobilization of the limbs in the trenches. It has not yet been seen in other than trench fighters. Some authors see in the condition only a neuritis *a frigore*, others a mechanical condition due to the leggings, puttees, overgaiters, or whatever leg wear is in use. Korbsch, doubtless having in mind the initial evidences of an infection, accuses recurrent fever, with a special localization of the spirilla in the blood of the extremities, while Grützer similarly makes it a local manifestation of influenza. The syndrome occurs with especial frequency in the flat-footed. It is admitted that the initial behavior does not differ from that seen in the onset of severe infections, as typhus and dysentery. Siegert has noted that subjects with edema of the limbs have a special predisposition. We can only conclude that we have here a syndrome which can occur under very opposite conditions.

Trench Hand.—Péré and Boyé have seen a number of cases of congelation of the hand in trench fighters, some of which ended in mortification. During severe bombardments men lie motionless for hours and snow is liable to fall on them and lie there. The hands have to grasp the musket and cannot be protected. Hours may elapse before they can be dried. Several forms of trench hand are recognized. In one the member is merely stiff and clawlike in attitude. A higher degree shows the same phenomena with addition of discolorations and at times phlyctnulæ. This form may end in exfoliation of the skin. In the gravest form the hand is entirely immobilized with mummification and moist gangrene, the two forms of gangrene coexisting. The discoloration and phlyctenulæ are seen in the terminal phalanges. —*La Press Médicale*, July 16.

Convalescent Malarial Soldiers and Farm Labor.—Jeanselme suggests that victims of malaria may recuperate as farm colonists. In infirmaries they become depressed and bored and should be given some kind of work or diversion. In regard to farm work they should possess some natural training or fitness for it. Picked men may then be placed in charge of abandoned farms. Naturally the men should be graded as to the kind of work. The sojourn of the individual will not be a long one, for he will soon be able to rejoin the ranks. The basic principle involved is, of course, a better convalescence for the soldier plus the advantages which accrue to the State in speeding agriculture.—*La Presse Médicale*, July 19.

Respiratory Tuberculosis and the War.—Much has been written on tuberculosis in the French Army, but careful analyses of personal experience with large material are not so common. In *Le Progrès Médical* for July 14 Morichau-Beauchant reports on his experience with 1206 cases of some form of tuberculosis of the respiratory organs seen by him during seven months (September, 1916 —April, 1917). The patients all came from the Ninth Army and comprised over two-thirds of all the chronic cases under observation. They were divided up as follows: 258 represented tuberculosis in the course of evolution; 948 arrested or non-evolutive tuberculosis. Of the first named 157 were examples of ordinary fibro-caseous phthisis while 74 others represented pneumonic exacerbations which have been termed necrotizing pleuropneumonia. There remains a small group of 28 cases of acute phthisis of which 3 were examples of acute miliary tuberculosis. The non-evolutive material is subdivided into 320 cases of fibroid phthisis, 171 cases of the attenuated, otherwise abortive form of the disease and 451 cases of tuberculous pleurisy. The latter type is of the greatest importance because it makes up over a third of all cases of so-called pulmonary phthisis. Nearly all of these cases (434) form a group of which little is known in literature. The affection is apparently a primary pleurisy which attacks young subjects and is practically of post-bellum origin. The subjects are pale, thin and weak. The cough is incessant, dry and more pronounced at night. The sputum is free from bacilli. A localized pain is present somewhere along the chest wall. The process is usually multiple, often bilateral. There is a tendency to enlarged lymph-nodes in the neck and axilla which is affiliated with tracheo-bronchial adenopathy. The *x*-ray invariably reveals enlarged nodes at the hilus but otherwise gives little information. Fever at night is seldom absent and sweating is habitual. The subjects usually present digestive disturbances, diarrhea, palpitation, headache, vague joint pains and low blood pressure. This type of affection runs an acute or subacute course with tendency to recovery. In not one case did true pulmonary tuberculosis develop. Adhesions invariably result and when these are present about the apex, apical tuberculosis may be simulated.

In about one-quarter of the 1206 cases the tuberculosis antedated the war (302). Of this number 117 had been sent back from the ranks for treatment or auxiliary service. An equally large fraction had remained at the front, having been equal to their duty. As a matter of fact nearly all of the 302 patients suffered from the non-evolutive form of tuberculosis and the balance presented a gradual type of evolution. Conversely the type of disease which appeared during the war was very largely evolutive. As these patients as a class had received antityphoid vaccination, this latter was often accused of lighting up the disease, but the author found but two patients in which this may have been the case. In like manner gassing may perhaps have determined three cases. The possibility that wounds and contusions could act as causal factors is not great, although now and then traumatism seems to light up an old focus.

The regimental surgeon should at once evacuate all cases of evolutive tuberculosis and this extends to all recent cases of any kind. The patients go to hospitals or sanatoria for treatment. Many subjects with non-evolutive tuberculosis (chiefly fibroid) have done good work at the front and have in time been evacuated for bronchitis, hemoptysis, emaciation, etc. Aside from the dry, benign form of pleurisy there is a certain amount of pleurisy with effusion which is almost always followed by pulmonary lesions and must be watched with great care. Complete recovery of cases of tuberculosis

under treatment may still leave the subject unfit for military service. On the other hand many subjects who actually suffer from non-evolutive forms are quite equal to duty at the front.

The Mobilized Dogs of the French Sanitary Service.—Grandjux in *Le Caducée* for August 15 asks what has become of the 120 dogs which once paraded before the public and asks why the complete silence concerning them. The question is often asked whether they have not made good, but to this he is able to answer in the affirmative. He states that some score of the first conscription of animals sickened or were withdrawn from service, so that about an even hundred of the original were really mobilized. On the other hand 80 new animals were drafted as a second contingent, so that 180 actually entered the service. The losses which occur usually take place in the first few days of mobilization. Dogs, like men, desert at times, but only when they have become separated from their masters, and before these have been replaced by others. Early in the war, when the armies were in retreat, the dogs could not be fully utilized. They have been useful in trench warfare, especially in locating wounded men at night. During the day rescue work of any kind is often impossible. The tendency of the dog to bark militates against the necessary quiet of rescue work. A good dog can, however, usually be trained to keep silence save when a shell explodes near him. In detail the possibilities of the dog are summed up in unofficial reports from the Fifteenth Army Corps early in the war. In Alsace they were of the greatest help to the stretcher men, fairly dividing the honors with them. This help was largely made possible because the fighting occurred chiefly in the woods, where the wounded might be readily overlooked. The dogs received many written testimonials, including one from Professor Tuffier. In addition to forest warfare the dogs were of great use at times after wounded men had been driven from the trenches. The Red Cross used dogs in the Balkan war and the Germans profited so well from this lesson that no less than 1,600 animals are said to be now in service in their armies. During the first few months of the war the dogs are known to have rescued over 3,000 wounded. In addition to discovery and signaling they carried first-aid kits. In summing up, the author defends the policy of silent rescue, in spite of the fact that the Germans train their dogs to bark on the discovery of a wounded soldier; if this were done by the French dogs, thus calling attention to the presence of a helpless "blessé," every bark would be a signal for a fusillade.

American Doctors Wounded in Air Raid.—The War Department announces that in addition to those killed in the air raid of September 4, on Base Hospital, No. 4, Drs. Rae W. Whidden of New York City, Thaddeus D. Smith of Neenah, Wis., and Clarence A. McGuire of Kansas City, Mo., all first lieutenants, M. R. C., sustained moderate wounds.

Elks Equip War Hospital.—The War Relief Commission of the Benevolent and Protective Order of Elks announces that it has been definitely decided to equip a hospital at Charlottesville, Va. This hospital is to be known as Base Hospital No. 41 of the University of Virginia. The hospital will be built and equipped at a cost of $60,000 and will care for 500 sick and wounded. This is the first of a number of hospitals which it is planned to equip from the $1,000,000 relief fund which has been raised by the Elks for this purpose.

Nursing Service in Camp Zones.—The Red Cross announces that it has assigned fifty public health nurses for duty in the zones around national army encampments. Nurses have already taken up their work in the districts around Hattiesburg, Fort Riley, Des Moines, Louisville, Ayer, Chillicothe, Atlanta, Newport News, and Petersburg. These nurses will endeavor to prevent the spread of tuberculosis and other infectious diseases. Besides the special work in the camp zones, Red Cross nurses in the town and country nursing service are at work throughout the country, especially in rural and mining communities. No less than nine bureaus have already been established for the supervision of special kinds of Red Cross activities in the States of New York, Connecticut, and New Jersey.

Changes in Organization of British Army Medical Corps.—The British Army Medical Corps is being remodelled to meet new conditions. A new branch is to be established to deal with questions affecting territorial and temporary medical officers. This branch will collect information on the many problems raised by the incorporation of so many civilian practitioners in the army medical service. These civilian officers to-day constitute eleven-twelfths of the army service and furnish one of the best evidences of the drain upon the man power of England. The United States has contributed greatly to the medical work in England, and the outlook at present is that even heavier contributions from this country will be required in the future.

Surgeon General's Office to Supervise Soldiers' Rations.—Surgeon General Gorgas has organized a food division in his office for the purpose of safeguarding the nutritional interests of the troops. This work will be carried on in cooperation with the Quartermaster's Department. It will include food surveys of each camp conducted by specialists in nutrition. Inspection will be made of the food received for soldiers' rations and a study will be made of the methods of preparation. The object of this undertaking is not only to prevent sickness through improper food, but to provide more healthful and appetizing meals. Some fifty or sixty commissioned officers will be engaged in making surveys of the camps and about twice that number of enlisted men will assist in the work which is to be under the supervision of Major John R. Murlin, assisted by Capts. Caspar Miller of Philadelphia, Frank C. Gebhart of New York and Lieuts. A. W. Thomas of New York and N. P. Blutherwick of Washington.

Care of Soldiers' Feet.—Announcement is made that the Surgeon General's office has arranged to give attention to the special care of soldiers' feet, with reference both to the proper fitting of shoes and the prevention of troubles incident to the work the men will do. Orthopedic surgeons have been detailed to the various camps to instruct soldiers how to care for their feet. The soldiers' feet are submitted to regular inspection by the members of the Medical Department, and special inspection after particularly hard periods of work.

MEDICAL RECORD.

TYPHOID FEVER IMMUNIZATION.

PROPHYLACTIC immunization against typhoid fever has long since become a recognized procedure for the prevention of this disease, not only in military medicine but in civil practice as well. While the measure has not attained the same importance among civil practitioners that it has with the army doctors, yet its value to the former is none the less great, a fact which is fortunately being appreciated more and more, particularly in localities where seasonal incidence of the disease is encountered periodically. It is not putting the case too strongly to state on *a priori* grounds that if the entire population of the country was vaccinated there is reason to believe typhoid fever would eventually disappear.

The therapeutic application of typhoid vaccines has been largely overshadowed by the brilliant results obtained when they are used prophylactically. However, successful treatment of the infection is just as important as its prevention. During the past two years Gay of California has published several articles along this line. In the July issue of *The Journal of Laboratory and Clinical Medicine* he summarizes his views regarding the preventive and therapeutic employment of typhoid vaccines. He maintains that the type of vaccine should be uniform throughout the country, and is best prepared from several strains of known immunizing power. In other words, the vaccine should be polyvalent, and contain strains of bacilli which have been shown to vary. If the vaccine is intended for army administration, it is considered advisable to put in paratyphoid (alpha and beta). It is probably unnecessary to include the paratyphoid vaccines in the immunization of civil communities. Some of the more important of Gay's recommendations as regards the immunizing treatment are as follows: The total dosage should include not less than 3,000 million of each of the organisms (typhoid and the two paratyphoids) employed, and should be administered in equal parts simultaneously. Recent results in Europe lead us to believe that the three vaccines may be given in doses as large as 1,000 million each. Under these conditions, three injections would suffice to complete the treatment, but if the reaction is too severe the dosage could be diminished and a larger number of injections be given. The injections should be given on alternate days, a method which would hasten the time of protection, facilitate the completion of inoculation of large numbers, and apparently produce as lasting immunity as vaccination at longer intervals. In order to determine the degree of immunity in vaccinated individuals, the typhoidin test may be utilized. Gay suggests that every person vaccinated against typhoid fever be tested one month after completing treatment by the typhoidin test, and if this is negative there will be need of further injection. Each individual should also be tested at yearly intervals in a similar manner. It cannot be claimed that the typhoidin test is absolutely specific, inasmuch as typhoid vaccinated persons may give a positive reaction with a similar preparation of paratyphoidin alpha. Despite this fact the test seems to be sufficiently indicative of protection to justify its employment as a valuable adjunct in prophylactic inoculation.

In connection with the therapeutic use of typhoid vaccines, opinions differ, which is to be expected, depending as they do upon the experience of those giving the vaccines, the type of the disease, the number of cases treated, and many other factors which have to be considered carefully before drawing conclusions. Gay favors the intravenous injections of sensitized vaccines as the procedure of choice, and has succeeded with this method in shortening the majority of cases of fever and in aborting the course of the disease in about one-third of the cases. Although the number of patients treated in this way has not been large, the reports available indicate that it is worthy of a thorough trial. The general consensus of opinion regarding the treatment is that, whatever its merits may be in effecting a speedy cure of the disease, it is at least free from harmful results if given with due regard to dosage and technique of preparation, so essential to the success and safety of any form of intravenous therapy.

INHERITANCE OF STATURE.

STATURE is dependent upon many circumstances. Age, sex, and race all contribute to differences in height. Also, as Charles B. Davenport points out in Bulletin No. 18 of the Eugenic Records office, there is a widespread belief that, within limits, growth in stature may be controlled by conditions of life. Hereditary factors involved in the differences of height follow from the recognition of racial differences, for true racial characters are hereditary. In the paper by Davenport some interesting phases of the subject are referred to. Among these is the control of stature by nutrition. Attention is drawn to the fact that variations dependent on this cause are due less to quantity than to quality of ingested food. In this connection the studies of Osborne and Mendel, published in 1914, are of great

importance. They found that if rats are given as much as they can eat of maize deprived of an amino acid and tryptophan they will cease to grow and will fall far behind their fellows who have received these materials. However, if the tryptophan be restored, even after the lapse of months, the little rats will begin again to grow and eventually will catch up with their fellows. That is, the specific growth factor works itself out when it is given a chance, in spite of the prolonged continuation of unfavorable conditions. Therefore, according to Davenport, underfeeding or improper food, in this country and among the class of people with which his statistics have to do, does not count for much in the ultimate result. Likewise, overfeeding, while it may influence weight, has probably little effect on adult stature; it simply may hasten growth and thus enable a man to reach prematurely his predestined stature. The comparative lack of dependence of growth on quantity of food is shown by the fact that a bantam chick, eat what it will, never develops into anything but a bantam fowl.

But, although the writer contends that food conditions have only limited and special relations to growth, this is not at all the case with internal conditions. It is known that variations in the amount of the secretions thrown into the body by various ductless glands have important relations to growth. Moreover, variations in the secretions of the gonads, the thyroid, the pituitary body, and the pineal body are very common and in the opinion of Davenport are hereditary, that is, racial. Since growth is so dependent upon secretions that, in turn, may be modified by numerous frequently occurring accidents, one might feel justified in doubting if any inheritance of stature can be traced. On the other hand, it must not be forgotten, first, that the degree to which the functioning of a gland is disturbed by bad conditions is not independent of hereditary factors and also the variations in the ordinary functioning of a gland are determined largely by such factors. Furthermore, it appears to be true that the minor dysfunctionings of the endocrine glands are unable to prevent the eventual working out of the organism's hereditary growth potentialities.

In the summary of conclusions, Davenport notes that one of the factors that determine variation in stature is probably the variation in age of onset of puberty. That parents of similarly deviant stature have on the average less variable offspring than those of one short and one tall parent. That the offspring of two tall parents are less variable in stature than those of two short parents. That, when both parents are "tall" or "very tall" and of tall stock, practically all the children are tall or very tall. That, when both parents are "very short" or "short" and of short stock, all children are short or very short. It is found that "short" parents may and frequently do carry germ cells which lack the shortening factors, while in tall parents the gametes are more nearly homogeneous and lack most of the shortening factors.

NIKALGIN.

THE European war has upset several more or less generally held notions in medical science and has given many a jolt to orthodoxy in surgical practice, the ultimate effects of which cannot yet be foreseen. The horrible condition of many of the wounds has been found to defy the ordinary aseptic treatment which works so perfectly in a well-ordered hospital, and new methods have had to be devised to meet the new conditions. Then again the fearful nature and great extent of the wounds have called for new pain-stilling methods. The usual anodynes and analgesics have failed to relieve the frightful suffering, and in desperation the surgeons have tried whatever came in their way regardless of the source of the new remedies. Thus many antiseptics were tried, and some adopted, that were prepared after secret or semi-secret formulæ; "ambrine" was extensively used for burns, to the inexpressible relief of the sufferers and of the humane hospital surgeons as well, although its manner of preparation was unknown; and now, as our Paris correspondent writes, another secret remedy has been tried for the relief of the exquisite pain attendant upon the dressing of extensive raw surfaces, and seems to have brought surcease to the most horrible torture.

The basis of this anesthetic is quinine hydrochloride, or more probably the familiar quinine and urea hydrochloride, combined possibly with other anesthetics. Perhaps it is something like the efficient local anesthetic devised by Dr. Douglas H. Stewart of New York several years ago, which consists of urea and quinine hydrochloride with novocain and adrenalin, a solution of which is devoid of the primary irritant properties of the unmixed quinine salt. Whatever it is, it appears to relieve suffering, and the fact that it is secret does not in the least affect its anesthetic action, however irritating it may be to those queer souls who would rather see their patients suffer bravely under pharmacopeial dosing than get relief from a "nostrum."

Ether was patented when its effects were first publicly demonstrated; Warburg's tincture cured malaria before its formula was known and introduced, in modified form, into the National Formulary; ambrine relieved burns while its composition was still unknown, and now many similar preparations, made after various formulæ, some secret and some open, do likewise. The history of nikalgin will doubtless be the same; it has been adopted in a number of the army hospitals on the western front, and according to apparently authentic reports has relieved the fearful sufferings of many a brave poilu; if this is true—and it seems to be—every man with a spark of humanity in his bosom must rejoice, and bless the man who forced the remedy upon the attention of the French army surgeons. Those who grieve because the formula and mode of preparation are secret may take heart of hope, for, as in the case of ambrine, the secret will soon no doubt be brought to light, and then we can all be happy.

Typhoid Fever in Rural Districts.

As a rule, typhoid fever is a greater menace to life and health in rural than in urban districts, a fact emphasized by most writers on the subject and proved by mortality statistics. The reasons for this are not far to seek. The public health is more carefully guarded, by far, in cities than in the country. The surface well and the open closet, absent from towns but common in the country, are potent means by which infection is spread. Soil may become infected through the excreta of a patient or a carrier, and may be conveyed to rapidly growing vegetables, and thus cause typhoid. Or the germs, by the agency of sudden, heavy rains, may filter into wells or streams. Moreover, it must be borne in mind that typhoid germs will live in the soil for a considerable period of time. According to Dr. S. F. Millen, writing in the *Dominion Medical Monthly* for September, 1917, the typhoid carrier causes, directly and indirectly, most of the rural outbreaks of the disease in the part of Ontario in which he resides. Indeed, he holds the view that the carrier is the main cause of typhoid in all rural districts, and that water and other transmitting agents are secondary to the carrier as a mode of disseminating the malady, serving merely as indirect channels for transmitting the infection from the carrier to the one infected. There is little doubt that the carrier does convey infection, but it is manifestly difficult to state to what extent he is a factor in the spread of typhoid. One cannot easily discard the established belief that the disease is water (and milk) borne. However, Millen is right when he asserts that the convalescent typhoid patient should be watched, and the necessary precautions should be taken until it has been demonstrated beyond question that he is no longer a carrier.

Exophthalmic Goiter.

The belief that Graves' disease is a disorder dependent upon an excessive or perverted secretion of the thyroid gland is so firmly accepted by the universal medical mind that any one opposing this view must argue well and cunningly if he would convince. The most recent opponent of the thyroid gland theory is Dr. Robert McCarrison, whose book on "The Thyroid Gland in Health and Disease" was published a short time ago. The author demonstrates to his own satisfaction, and doubtless to that of all who think with him, that Graves' disease is not primarily a disease of the thyroid gland, not essentially a hyperthyroidism, but that the underlying condition is a toxemia due to intestinal stasis. Consequently, in logical accordance with this view, surgical interference with the gland itself is not justified. Rather, should the seat of the evil be attacked medically with petroleum oil and an intestinal antiseptic, or by operative procedure in the abdominal region. Arbuthnot Lane has held for a long time that Graves' disease originated in the intestines, and now McCarrison advances the same view. It may be pointed out that exophthalmic goiter is vastly more frequent among women than men, as also is intestinal stasis. This may be no more than a coincidence, but it is a suggestive coincidence. The author's thesis is entertainingly, if not always absolutely convincingly, sustained.

News of the Week.

Infantile Paralysis in Chicago.—On September 20 there were in Chicago 139 cases of infantile paralysis under observation, and 20 deaths from the disease were reported to the Health Department during the preceding four days. According to Commissioner Robertson the disease shows unmistakable signs of being on the increase.

Typhus Fever in German Prison Camps.—A French soldier recently escaped from a German prison camp brings the report that 3,700 French and British soldiers, and 1,500 Russians have died of typhus fever at the German concentration camp at Cassel.

The Automobile as an Agency of Death.—The Metropolitan Life Insurance Company has just disclosed the results of a study of the deaths due to automobile accidents among the industrial policyholders since 1911. The fact is revealed that during this five-year period the death rate from this cause has tripled. In 1911 the death rate from automobile accidents was 2.3 per 100,000; in 1916 it had increased to 7.4. During this period the rate each year was markedly higher than for the preceding year. Nearly one-third of those killed were children under ten years of age. There were more deaths caused by automobiles among the industrial population than by surface cars, subway trains, elevated trains, bicycles, and horse-drawn vehicles combined. These figures represent almost exclusively pedestrians rather than those who ride in the machines.

Broad Street Hospital Open.—The New Broad Street Hospital has been opened for the reception of patients. The hospital is seven stories high and as now equipped represents an outlay of $270,000. Of this amount $200,000 was contributed by James Barbour. The hospital was established to provide for the needs of the people in the south end of the city, extending from the East to the North Rivers and as far north as Canal Street. The hospital has two motor ambulances and a thoroughly equipped dispensary. Dr. A. J. B. Savage is superintendent. A number of private rooms have been endowed.

Dr. George W. Stoner, Surgeon United States Public Health Service, who has been in charge of the Marine Hospital at Stapleton, S. I., for the past four years, has been retired from active duty, having served forty years. Dr. C. H. Lavinder is now in charge at Stapleton.

Decrease in Belgian Birth Rate.—The heavy increase reported in the death rate in Belgium is accompanied by a corresponding decrease in the birth rate. In the Brussels district, in 1913, there were 6,417 births, an average of 17 per thousand population and a death rate of 13.7 per thousand. In the first six months of 1915 the birth rate was 14.3 and the death rate 14 per thousand inhabitants. In the corresponding period of 1917 there were 3,311 births, an average of 8.5, and a death rate of 19.3.

Health of the Navy.—The report of Surgeon General Braisted of the Navy shows that the health of the men in the navy is very good. Some cases of measles continue to be reported from the Atlantic fleet. Measles is less prevalent than mumps, averaging only ten new cases a week for

the whole force afloat. There are a number of cases of measles and mumps reported from the naval training station at San Francisco.

Scarcity of Rubber Gloves in England.—The shortage of rubber operating gloves in England has become so serious that unless the United States is allowed to send larger supplies very bad results are threatened. The situation has arisen from the fact that the Board of Trade has forbidden their importation. Since the restriction was imposed the army and navy have been supplied under special license, but even the naval and military surgeons have not enough, while the local hospitals are being forced to dangerous expedients. The British Medical Association has made an appeal to the Board of Trade urging license, permitting the civil hospitals to get supplies from the United States.

A Plea for the Conservation of Pharmaceutical and Biological Products.—The Committee of Public Safety of the Commonwealth of Pennsylvania has sent out letters and circulars urging the wisdom of eliminating waste in the handling of pharmaceutical and biological products. It calls attention to the fact that biological products, such as serums, antitoxins, serobacterins, and bacterins as well as all kinds of vaccines, are subject to deterioration and when they are once outdated are of no use whatever. It is, therefore, essential that these products be not stored in excess of reasonable requirements. Many galenical preparations are also subject to deterioration, particularly the fluid extracts and other preparations of ergot, digitalis, and strophanthus. These preparations should, therefore, be ordered in sufficient quantities to last not longer than six months. Cards have been sent to all the retail druggists in the State of Pennsylvania asking them to pledge themselves to cooperate in this particular item of conservation. It is one in which physicians also may do their part.

Indictments in Diploma Case.—Further investigations with reference to the alleged diploma factory where it is possible to purchase certificates, college diplomas, and licenses to practise medicine, have resulted in additional indictments against the chief offender and his wife and several accomplices. One man had in his possession a diploma for which he had paid $1,600, which purported to be from a medical institution of high standing in Vienna, Austria.

The Lincoln Hospital and Home, New York, will receive $100,000 and the New York Orthopedic Hospital $50,000 under the will of Mrs. Helen Cossitt Juilliard, upon the death of her husband. One-fourth of the residue of her estate and $100,000 are to go to St. John's Guild upon the death of Mr. Juilliard.

Dr. Rudolph Duryea Moffett has removed to 70 East Seventy-seventh Street, New York City.

The Association of Military Dental Surgeons of the United States will hold its annual meeting at Hotel Astor, New York, on October 23. All dentists who have taken their examinations for the Dental Reserve Corps, whether they have received their commissions or not, are invited to attend.

The American Association of Clinical Research at its recent meeting in Boston elected the following officers for the ensuing year: *President*, Dr. Marshall W. McDuffie of New York; *First Vice-President*, Dr. Roger M. Griswold of Kensington, Conn.; *Second Vice-President*, Dr. Joseph A. Weitz of Montpelier, Ohio; *Secretary-Treasurer*, Dr. James Krauss of Boston. The next annual meeting of the association will be held in New York in October, 1918.

Dr. Bertram H. Waters, formerly chief of the Tuberculosis Clinics of the New York City Department of Health, has been appointed physician-in-chief of the Loomis Sanatorium, to succeed the late Dr. King.

Medical Association of the Greater City of New York.—A stated meeting of this association will be held at the New York City Children's Hospitals and Schools, Randall's Island, on Monday afternoon, October 15, 1917, at 3.00 P. M. The island is reached by ferry from East 125th Street Pier, at termination of 125th Street Crosstown line. Boats will leave at 2 P. M., 2.30, 2.45, and thereafter on the hour and half hour.. The following papers will be read: "Practical Talk Upon the Differentiation and Care of the Feeble-Minded, including the Moron, with Demonstration of Types," by Dr. William Burgess Cornell, medical director New York City, Children's Hospitals and Schools; discussion by Dr. Walter E. Fernald, the Massachusetts School for Feeble-Minded, Waverley, Mass; "The Care, Management, and Treatment of Epileptics," by Dr. L. Pierce Clark; discussion by Drs. Charles L. Dana, George H. Kirby, and Clarence O. Cheney.

Symposium Upon Neurological Surgery.—This will be held in the surgical amphitheatre of the New York Polyclinic Hospital on October 1, 1917, at 8.15 P.M., by the Department of Neurological Surgery. The following papers will be presented: "Diagnostic Value of Lumbar Puncture," Dr. Y. C. Lott; "Observations Regarding the Anesthesia in Cerebral Surgery," Dr. Charles S. Hunt; "The Appearance of the Fundus Oculi in Certain Intracranial Conditions," Dr. J. A. Kearney; "Presentation of Patients Operated Upon for Various Intracranial, Spinal, and Peripheral Nerve Lesions," Dr. William Sharpe; "Psychopathology," Dr. Edward S. Cowles; "The Treatment of Hypoplastic and Mentally Impaired Children," Dr. E. Bosworth McCready.

Operative Clinics at Greenpoint Hospital.—Dr. Frederick C. Holden announces a series of operative and demonstration clinics in the department of gynecology and obstetrics of the Greenpoint Hospital, Brooklyn, N. Y., to be held Thursday afternoons at 2 P.M.

Straus Milk Depots Complete Twenty-five Years' Work.—With the close of the Straus milk stations for the summer, Nathan Straus has rounded out twenty-five years of this work, during which 44,940,907 bottles and 25,305,519 glasses of pasteurized milk have been dispensed. The largest work of the summer has been at the Straus depot in City Hall Park, where an average of nearly 50,000 glasses of milk were dispensed daily. There are eight Straus depots, which will continue as usual throughout the winter months.

Obituary Notes.—Dr. JACOB M. MORIN of Brockton, Mass., died at his home in that city on September 12, at the age of 48 years. He was a graduate of the Long Island College Hospital in 1899, formerly president of the Brockton Medical Association, and a member of the staff of the Brockton Hospital.

Dr. STEWART W. ALDRICH, one of the oldest physicians of Des Moines, Iowa, died September 3. He was a graduate of the Cleveland, Ohio, University of Medicine and Surgery, in 1874, and practised for some years in Waukee, Iowa.

Dr. PRAMATH N. ROY, a graduate of the University of Glasgow, in 1885, and for thirty years a practitioner of Charlestown, Mass, died of heart disease, on September 5, aged 58 years.

Dr. JOHN B. ROBERTS, a graduate of the Medical College of the State of South Carolina, in 1867, died at his home in Atlanta, Ga., August 30, aged 76 years. At the time of his death he was physician at the Soldiers' Home in Atlanta.

Dr. DELPHIN BIENVENU, a graduate of Tulane University, in 1878, and a Confederate veteran, was killed in an automobile accident, on September 2. He was 81 years of age and retired from practice some years ago.

Dr. JOHN D. BAY, a graduate in medicine and law of the University of Valparaiso, Ind., died in the Boise Hospital, Boise, Idaho, August 30. He had ceased to practise medicine some years ago and was interested in mining in Colorado.

Dr. EDSON CARD, a practising physician of White Plains, N. Y., died at his home in that city, on September 9, aged 60 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1882.

Dr. HENRY A. SALMON, a graduate of Bellevue Hospital Medical College, in 1888, died at his home in New York City, on September 10, aged 59 years.

Dr. WILLIAM F. MCDOWELL, chief pharmacist of the United States Immigration Department at Ellis Island, died on September 11, aged 65 years. Dr. McDowell was a medical officer in the service of the Government during the greater part of his life, having commenced as the medical officer of the U. S. S. *Monongahela*. He was also connected with the United States Marine Hospital at Portland, Me., for a number of years.

Dr. JEROME S. BISSELL of Torrington, Conn., a graduate of Yale Medical School in 1894, died after a long illness on September 14, aged 48 years.

Dr. HUGO KINNER died at his home in St. Louis on September 11, of pneumonia. He was a graduate of the University of Berlin, in 1863, and celebrated his golden jubilee as a doctor in 1913 when the university conferred an honorary degree upon him.

Dr. JOHN C. CHAMPLIN, a graduate of the Boston University School of Medicine, in 1885, died at the home of his sister in Block Island, R. I., September 14, aged 53 years. He was prominent in the political affairs of his locality and for many years president of the Town Council.

Dr. JAMES R. SHARMAN, a graduate of the Louisville Medical College, in 1876, died of heart disease at his home in Meridian, Miss., September 4, aged 65 years.

Dr. WILLIAM D. SILKMAN of Manhattan, Kan., a graduate of the New York University Medical School in 1893, died of injuries sustained in an automobile accident, on September 7.

Dr. JOSEPH F. LINDSEY, a graduate of Harvard Medical School in 1876, and a member of the Massachusetts Homeopathic Medical Society, died at his home in Roxbury, Mass., September 8, aged 67 years.

Correspondence.

REEDUCATION OF WAR CRIPPLES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The Surgeon General directs me to invite your attention to the inclosed copy of a letter which has been sent to secretaries of all County Medical Societies. He requests that the letter be published in the MEDICAL RECORD at an early date, with request to readers to send to the Surgeon General short life histories of any partially handicapped persons who have been successful. Names of the handicapped are not at all necessary.

Any successful handicapped who desire to furnish autobiographies will be rendering great aid.

C. L. FURBUSH,
Major, M. R. C.

OFFICE OF THE SURGEON GENERAL,
WASHINGTON, D. C.

1. The Surgeon General directs me to invite your attention to the following:

2. He is arranging for special treatment for wounded including special efforts for functional restoration of damaged parts and vocational reeducation for those who, from the nature of their illness or injury, are unable to follow their previous occupation.

3. It will be a very great help if he can know just what those who are suffering from chronic illnesses or who are partially disabled as a result of injuries are now doing in the United States. As example, one having lost the right hand may still be a successful carpenter or a market gardener; one having lost both lower extremities may be successful in some line; one with chronic heart disease may have found a suitable occupation. The collection of this experience should be of remarkable assistance as showing what the various types can do.

4. The Surgeon General very earnestly requests that the Medical Society, of which you are secretary, aid in this matter by getting, through its members and the various local agencies, a list of the partially disabled in your county who are successfully following a trade or occupation. The information desired in reference to each case is as follows: (*a*) Character of disability, medical or surgical. (*b*) At what is the patient employed and how successful is he? (*c*) In what way did he learn or enter his occupation after his injury or illness? The names of the disabled are not necessary.

5. If any man who has been successful after an injury or illness desires to write a short autobiography stating his experiences the same might be exceedingly useful in this work, in preparing a booklet to be distributed to the men at the proper time.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE LORD ROBERTS WORKSHOPS—CARGO ACCOMMODATION FOR THE RED CROSS.

LONDON, August 30, 1917.

THE Lord Roberts Workshops in Fulham Road were established to provide life-occupation for disabled soldiers and sailors—not as a teaching center for the supply of skilled handicraftsmen. The last annual meeting was presided over by Princess Christian when the managing director, Major Algernon Tudor Craig, made so interesting a speech about the work that he was asked to give facilities for personal inspection and gladly did so. A surprisingly interesting time was spent at the works under his guidance. The establishment was opened in March, 1915, and the great effort to provide the memorial fund is a matter of quite recent history. They produced about £162,500, and it is good to know that both the London Central and the Pro-

vincial branches are conducted in a way which has given much satisfaction. Last year a net profit of £965 was received and devoted to the purchase of a house next to the workshops, to be used as a small sick bay, in which the men will be able to receive on the spot that attention in the form of electricity and massage which their disabled condition requires. In the shops themselves the atmosphere is one of well directed activity, yet visitors must look closely to detect any sign of inaptitude due to a missing hand or arm. Toy making, cabinet work, skilled carving are examples, such as an oak overmantel with family crest and motto. So basket work, box making and manufacture of furniture are some of the industries followed. The provision of wonderful up-to-date machinery, which is of itself a treat to see, enables the eight hundred workers to turn out such a quantity of goods that the list of firms keeping them on sale fills a pamphlet.

Mr. Petterolt, freight traffic manager of the International Mercantile Marine, has been appointed manager of the ocean shipping for the period of the war. He will give his services without remuneration. Practically all the cargo space needed has been placed at the disposal of the Red Cross. Much of this will be given free by the steamship companies and the allied governments.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

A NEW LOCAL ANESTHETIC—AMERICAN RED CROSS—ARMY Y. M. C. A.—MACEDONIAN MALARIA.

PARIS, Aug. 28, 1917.

MORE than a year ago, while I was staying at the Hotel Majestic, in New York, I met a Mr. Gordon Edwards from California, who, I was told, was trying to introduce into the French Army Medical Service a preparation of quinine for purposes of local anesthesia. Knowing that this drug had long been used as an anesthetic, and having met numberless men who were trying to introduce something or another to the Government, I took no interest in the new preparation, and rather avoided the gentleman in question; but, learning recently that after many and persistent efforts not only had he succeeded in introducing the new remedy, but that it was reported a great success, I looked the matter up to inform myself as to facts. I found that he had something called "Nikalgin," which seemed really to fill a much-felt want.

Nikalgin is a non-toxic local anesthetic solution of quinine chloride, and capital results have been obtained in the treatment with it of fresh exposed raw surfaces of shell wounds, burns, lacerations, and amputated stumps. By simply spraying the affected parts, or by the application of a saturated pack, anesthesia is produced, and endures for from three to twenty-four hours. Men even in the worst condition very seldom require more than five to seven applications before they are on the way to improvement, because the relief from pain renders recovery more rapid.

Mr. Edwards, who is from Leland Stanford University, California, had been studying the anesthetic properties of quinine for nearly two years before the war, and just after the outbreak he set about producing the solution for spraying raw surfaces, which has brought such relief to the wounded. It is estimated that 100,000 men have already received the treatment. He first went to England, and then came to France, and after nearly two years of fruitless efforts with officials in both countries he finally began work with his own hands in field and base hospitals, proving to surgeons by demonstrations the value of the solution.

The two surgeon-generals of the armies at Verdun and the Chemin des Dames adopted the treatment, and since then all of the hospitals under their control have been supplied through the generosity of Miss Anne Morgan and her societies and friends in New York. Mr. Edwards has assured all the hospitals now using the remedy that he will continue to supply them gratuitously until the end of the war. The first case in which the quinine solution was used was one known to nurses and surgeons as "the Zouave," which designated a patient whose suffering during the dressing of wounds was almost more than man could bear. Down the length of his hip and leg were a dozen great raw wounds from a shell burst, and the gauze dressing had to be removed daily. The gauze was saturated with the solution, and within three minutes the surgeons had begun to peel the dressings from the wounds. The operation was completed without a murmur from the patient, and the surgeons were as happy as the patient.

The Surgeon-General of the Army at Verdun wrote: "I have the honor to send you the reports which have reached me from the ambulances in which I have experimented with nikalgin. The application was very effective on a burned man having large naked surfaces. The médecins-chefs are unanimous in acknowledging that nikalgin produces in a few minutes a diminution of pain, which has disappeared entirely after five or ten minutes." This remedy is said to be useful only when applied to denuded surfaces; it does not replace other well-known local anesthetics for purposes of surgical operations.

The American Red Cross has not only established canteens for the American soldiers wherever it is essential to have them, but is also cooperating with the Convois Auxiliaries de la Croix Rouge Française (S.S.B.M.) in the support of canteens for French soldiers immediately at the front. These canteens are established behind the front, as close to the second line of trenches as possible or at a junction of roads leading to these lines. They serve out hot and cold drinks, coffee, bouillon, cocoa, lemonade, etc., to the men passing to and fro. They also send out the "marmites norvégiennes," which contain hot or cold drinks, to as many points as the post can cover in its sector, and this service is carried on by the use of small automobile trucks.

As many as 2,000 to 3,000 rations are served a day at an ordinary canteen post. The intention is not only to supply hot and cold drinks, as at present, but also food, and, if possible, to make the post a real rest and recreation center for the men by having tobacco, writing materials, games, phonographs, etc. Each canteen is in charge of a convoyer, with the help of two or three men furnished by the army, and it is proposed to have as many American convoyers as there are French.

The determination of the Red Cross to absorb and manage all of the American Relief Work in Paris came as a surprise to the great army of American workers employed and at first caused many heart burnings, but seeing that they must bow to the inevitable, the Women of the American Colony have organized, under the presidency of the wife of the American Ambassador, "The Woman's War Relief Corps," under authority from the Red Cross. All American women and American women whose husbands are citizens of subjects of Allied nations are eligible to membership. The organization will be under the management of a board of directors. These directors will be in charge of the different corps divisions, which will consist of canteens, diet kitchens, general information and reclamation bureau, trained nurses, auxiliary nurses, propaganda and records, publicity department, refugees (adults and children), registration bureau, social service, Red Cross circles, which include Red Cross chapters, ouvroirs and workrooms, surgical dressings, blind. The underlying principle and obligation of membership is that women shall give their services to the utmost of their ability. The first one thousand applicants to register will be called charter members.

The American soldier is due to have a big surprise when there arrives in his training camp a huge canteen on wheels supplied by the American Y. M. C. A. Although the Y. M. C. A. buildings are springing up like Indiana mushrooms wherever there are American soldiers, the Y. M. C. A. felt that every soldier must have an immediate opportunity to supply his needs. The "canteen on wheels" is loaded with towels, soap, razors, chocolate, crackers, games, newspapers, 5,000 novels, 70,000 francs worth of tobacco, and many other articles which the boys are longing for. A Y. M. C. A. secretary is in charge of the canteen. The Paris headquarters are located at 21 Avenue Montaigne and it has an "Airdome" located in the courtyard in which is located the tea garden. They give different forms of entertainment nightly. It is difficult to decide which the soldiers most enjoy, the movies, the ice-cream and refreshments, or the music supplied by a volunteer three-piece orchestra. It is evident that the entire neighborhood appreciates the proximity of the Avenue Montaigne headquarters.

At the monthly meeting of the Academy of Medicine Dr. Marchoux presented an interesting memoir on malaria. He began by showing that the malaria of Salonica has nothing about it that is mysterious, as has been pretended by certain of the army surgeons. It is caused by the agents discovered by Laveran, as are all the varieties of this disease. He claims that it is best treated by basic quinine, rather than the soluble salts. The schizontes are destroyed in the process of evolution and the gametes persist, producing the fever after fourteen days of incubation. The parasites become visible to the microscope three or four days prior to the access, in time to abort the attack by the employment of quinine in four to five-grain doses. At times it fails to ward off the attack, but even in these cases it controls the temperature so that the fever is hardly noticeable. In locations too far distant from laboratories to permit of regular and frequent examinations of the blood, to determine the propitious moment to begin the quinine treatment, he claims that the administration of three doses per week during a period of several months will suppress the evolution of the parasites. This would, therefore, seem to be the safest and simplest course to pursue.

1. The Modern Treatment of Burns, with Special Reference to Severe Burns and the Use of Ambrine and Its Substitutes.—Edward Hammond Risley bases this study on a personal observation of a series of cases treated in the Massachusetts General Hospital since 1914, and upon the tabulation of all burned cases treated at the hospital for the past ten years. He concludes that the three most important factors in the treatment of burns are: (a) Prevention of shock. (b) Prevention of sepsis. (c) Prevention and Treatment of Contractures. 2. Many deaths have been caused by ill-advised attempts at first dressing. 3. The form of first dressing is largely responsible for subsequent sepsis. Oily dressings should be avoided. Cleansing the skin surrounding the burned area with alcohol aids in preventing sepsis. Constant drainage of discharges is essential. 4. The open-air treatment is far superior to that in which any form of dressing is used. 5. Either picric acid or Tr. chloride of iron are by far the best forms of medicated dressing. 6. Contractures can be prevented in 75 per cent. of the cases formerly contracting by the early use of properly adjusted splints and by early passive motion and massage. 7. Duodenal ulcer is a rare complication and can be almost discounted. The writer formulates the following general rules for treating burns: 1. Combat shock. 2. Treat all shocked cases or those with extensive burns by the open-air method or the temporary use of the hot bath. 3. Avoid oily dressings. 4. In burns of the extremities, if fairly extensive but not requiring open air, use picric acid. 5. In all other burns use picric acid, Tr. chloride of iron, or the more modern paraffin film treatment, according to preference or experience. Ambrine, not being on a strictly ethical basis, was investigated. Analysis showed that it contained roughly 90 to 95 per cent. of paraffin of a good grade, about 5 per cent. of beeswax, and a small amount of resin, and probably some such product as eucalyptol and an analine coloring matter. From the writer's experience with ambrine in the treatment of burns it would seem that its favorable effect was due purely to its mechanical action. It seems probable that this mechanical action is favorable because it immobilizes the affected area, because it makes a sterile dressing; because it makes an air-tight sealed dressing, which may possibly be the reason it does not favor bacterial growth, and because of its close adhesion to the part it favors in growth of granulations. From his limited experience with paraffin preparations the writer states that he has been converted from skepticism to a rather firm belief that this method of treating burns, certainly those of limited area, is a decided advance over the methods formerly employed.

4. Report of Result of Radium Treatment at the Collis P. Huntington Memorial Hospital by the Cancer Com-

mission of Harvard University.—William Duane and Robert Greenough present this report, which gives the detailed results of the use of about 235 milligrams of radium in the treatment of 642 cases of cancer and allied conditions at the Collis P. Huntington Memorial Hospital, from September, 1913, to January, 1916, from which they conclude that many cases of advanced, inoperable, or recurrent cancer may be given benefit by treatment with radium. The relief may include relief of pain, diminution of discharge, relief of hemorrhage, diminution in the size of the tumor mass, even to their total disappearance, and improvement in the general condition of the patient. To these must be added the beneficial psychic effect upon the patient. In a very small number of advanced cases improvement may occur such as to permit a radical operation. In about 35 per cent. of superficial and non-metastasizing types of cancer, and in a much smaller number of metastasizing cancers radium is capable of destroying the clinical manifestations of the disease. In a limited number of cases recurrence has taken place even after apparent destruction of the lesion. In keratoses, papilloma, and other benign skin diseases, regarded as precancerous, radium is effective in destroying the clinical manifestations of the disease in from 48 to 60 per cent. of the cases. In myelogenous leucemia the beneficial effects of radium are pronounced, and although the recurrence of symptoms may take place the clinical advantages of the radium therapy are very marked. In malignant lymphoma, lymphosarcoma, and Hodgkin's disease, the lesions appear to be especially sensitive to radiation, and definite, though temporary, relief is obtained. Radium has proven of special value in recurrent or inoperable carcinoma of the cervix or of the body of the uterus, inoperable squamous carcinoma of the tongue, jaw, and buccal mucous membrane, and in non-metastasizing epidermoid cancers. Radium therapy has been of little benefit in recurrent or inoperable carcinoma of the breast, stomach, or intestine, glands of the neck, cancer of the tongue, mouth, and lips, and in deep-seated metastatic extension of cancer from any region. The use of radium in the prophylaxis of recurrence after operation is not advised. Where the affected area is superficial and accessible it may be used with benefit, but not after operation for breast cancer. The combination of radium therapy and operation has yielded satisfactory results in several cases, and is adapted to the more advanced cases of rodent ulcer. In 642 cases treated with radium in this series 354, or 55 per cent., received definite benefit.

8. Hygiene of Rural Schools. J. A. Nydegger.

3. Conclusions Drawn from a Comparative Study of Different Methods of Performing the Wassermann Reaction.—J. Bronfenbrenner and M. J. Schlesinger call attention to some of the numerous discrepancies in the methods of performing the Wassermann reaction, and express the belief that the removal of the differences in methods can only be brought about by an extensive comparative study. They have made such a study on over 20,000 cases. As a result of this study they recommend a procedure which makes use of fresh unheated serum. The complement of the serum is titrated and utilized in the test, guinea-pig complement being added when necessary. They use precipitated acetone insoluble lipoids, of which one-tenth the anticomplementary dose still contains ten to 100 antigenetic units. The antihuman hemolytic system is used and the erythrocytes are sensitized before being added to detect the presence of free complement. Incubation for fixation of complement is best performed for thirty minutes at 37° C. in the water bath. However, one can use ice-box incubation for ten to fifteen hours as a presumptive test to eliminate the negative serums, and 37° C. incubation for five minutes to eliminate the strongly positive serums. For diagnosis the one-half hour incubation at 37° C. is best.

5. The Use of the Term Hysteria.—Meyer Solomon points out the reasons why the term hysteria should be abolished. He says that hysteria as a word is etymologically unscientific when applied to any of the phenomena which have been classified under this name, since it harks back to the days when the uterus was incriminated as the cause. It recalls the days when hysteria was synonymous with simulation. It must be discarded because of the heterogeneous clinical group of manifestations in the purely psychological sphere and in the sphere of the voluntary and involuntary nervous systems which have been packed into this group. No unanimity or agreement can be reached as to the delimitation of the clinical concept to be given this name. It would seem therefore that there is no way out of the dilemma other than to do away with the term once for all. The writer then proceeds to a disintegration and arrangement of the conditions hitherto massed together by different students of this problem. He finds that these disorders are usually in one or more of four spheres. These are: 1. Ideational processes. 2. The feelings with their specific attitudes. 3. Disturbance of the voluntary sensorimotor nervous system. 4. Disorders of the involuntary sensorimotor and vegetative nervous system. One must be able to exclude all possible causes except emotional shock and trauma before attributing the disorders under consideration to emotogenetic factors. The writer claims that his classification means that in all cases of so-called hysteria one must make a careful investigation as to the possible mental state of the person presenting the symptoms, and as to the genetic factor or factors responsible for the evocation of the particular picture which is to be diagnosed. Of course, there may be a combination of two or more of these types of reaction in the same person.

7. Causes of Appendicitis.—Henry P. DeForest says that while some of the causes of appendicitis are still obscure, certain facts are definitely known which seem to predispose to this disease. He believes that if the proper hygiene of nutrition is observed it will go a long way toward warding off this disease. He especially warns against irregular meals and too rapid eating, and also against the use of too finely prepared foods. In summing up he says the disease may be due: 1, to infection from the presence of one or more of the intestinal microorganisms; 2, to circulatory disturbances, more or less readily produced by sharply curved or angular shapes of the organ, or a deficient blood supply; 3, to the presence of accidentally imprisoned fecal matter, which is prevented from returning to the cecum both because of the feeble expulsive power of the tube, due to an insufficiency or entire absence of circular muscular fibers, and because of constriction of the tube, which may or may not be due to previously existing inflammation. This fecal matter, because of bacterial infection which it conveys to the parts or because of the pressure effects due to inspissation or both, contributes to the etiology of the disease in its entirety, but particularly in the cases in which perforation takes place. All pain in the right side is not necessarily due to appendicitis. It is quite as often due to indigestion with resulting colic. A tablespoonful of castor oil with an equal amount of glycerin in a glass of iced lemonade can be taken at once by a person who believes he has appendicitis. It can do no harm, and will effectively clear up the diagnosis. Many an attack of appendicitis has been eliminated by this procedure. Once the diagnosis has been made, however, the sooner operation is performed the better.

6. **Indications for the Mastoid Operation in Acute Otitis Media.**—Edward B. Dench says that every physician should remember that every case of acute mastoiditis is in reality a mastoiditis, and if incision of the drum is not followed by recovery drainage through the mastoid is indicated. If after free and, to the surgeon, satisfactory incision of the drum, pain persists from twenty-four to forty-eight hours, this is sufficient indication for opening the mastoid. A persistent high temperature, or a remittent temperature with exacerbations, naturally calls for exploration, but the point should be emphasized that many cases run an afebrile course, and the absence of an abnormal temperature is no contraindication to operation. Early tenderness, within twelve hours after the inception of an acute otitis, is not an indication for operation. One sign which is particularly significant is a recurring tenderness. This tenderness is first found at the tip, and is most severe here. Antrum tenderness is insignificant. The signs found on instrumental examination are to the author most significant of all. These consist of evidence of insufficient drainage of the tympanomastoid space through the small incision in the drum membrane, and narrowing of the canal at the fundus, that is, a persistent bulging of the upper and posterior portion of the drum membrane, with a sinking of the corresponding adjacent meatal walls. This sign present ten days after the inception of an acute otitis is an almost pathognomonic indication for operation. A bacteriological examination of the discharge gives much information. Staphylococci and large bacilli are undoubtedly canal contaminations, but the *Streptococcus capsulatus* is always a dangerous organism. The sudden cessation of a discharge, with the canal signs indicative of sudden interference with drainage is an indication for immediate operation. A history of spontaneous rupture of a drum membrane and a purulent discharge lasting five or six weeks, and also a history of repeated incisions are conditions calling for operation. In obscure cases meningeal symptoms may give the key to the situation. The author finds roentgenoscopy valuable in all cases of mastoiditis.

7. **Tyramine as an Adjunct to Morphine in Labor.**—Henry Gray Barbour states that the employment of morphine in labor has become frequent in recent years. It exhibits in this connection three important effects, the first desirable and the other two untoward, namely, analgesia, respiratory depression in the child, and delay of labor. In view of the value of morphine in labor it would seem that a substance having actions more clearly understood than those of scopolamine might be found which might be combined with morphine. The use in this connection of tyramine has been suggested by the study of Bry, and the author and his collaborators have made a series of experiments in animals and have observed a small number of cases in human beings in which this drug was used in connection with morphine. The dosage employed was 10 mg. of morphine sulphate with 40 mg. of tyramine. In the absence of contraindications this injection is given when discomfort becomes marked in the first stage of labor. Analgesia seems to be as complete as when the same dose of morphine is given alone. The respiratory rate of the mother is increased rather than decreased, and usually remains somewhat accelerated throughout. The condition of the children has been quite satisfactory, no tendency to asphyxia having been observed. In every case the frequency of uterine contractions has been increased within five minutes after the injection, and this augmented activity remained throughout. Forty milligrams of tyramine produces a temporary rise in blood pressure, usually amounting to 20 to 25 mm. This seems to be negligible in normal cases, but should be followed closely. It is hoped that more complete data can be offered soon; in the meanwhile there seems to be no objection to the employment of tyramine and morphine by those who are thoroughly versed in the use of morphine in labor.

9. **Serum Therapy for Trichinosis.**—Benjamin Schwartz refers to Salzer's seemingly successful results with serum therapy in the treatment of trichonosis and describes his own experiments which have given quite contrary results. He summarizes his finding as follows: 1. Serum from animals convalescent from trichinosis when injected into other animals did not produce immunity to trichinosis in the latter. 2. Trichinous meat mixed with serum from animals during the active or convalescent stage of the disease proved to be still capable of producing the disease. 3. Animals once infected and harboring trichinæ in their muscles were not immune to further infection when fed trichinous meat. 4. Serum from a trichinous animal had no observable ill effects on the larvæ freed from their cysts by artificial digestion.

1. **Observations on Trench Nephritis, Its Later Stages and Treatment.**—J. Mitchell Clarke presents an analysis of 80 cases admitted to the hospital with the diagnosis "nephritis." Of these there were only six in which the diagnosis was at fault. The remaining 74 were placed in four groups: 1. Thirteen cases in which there was either a distinct history of a previous attack of nephritis or definite signs of an affection of the kidneys of some standing. 2. Ten cases in which the nephritis was found to have cleared up on admission, though the symptoms of an attack before admission were quite definite. 3. Nineteen cases which completely recovered in hospital and were discharged cured. 4. Thirty-two cases which left this hospital not cured, though the majority were greatly improved. Of 68 patients three died, eight were discharged slightly improved, but as permanently unfit, and 11 much improved, but the urine contained casts and more than a trace of albumin, six were fairly well and able to do light work, and 32 recovered completely. In regard to eight patients there was insufficient information. In cases of nephritis at a base hospital the general clinical features perhaps especially characteristic are the benign character of the nephritis in the large majority, the frequency of pulmonary complications, especially bronchitis, edema of the lungs and bronchopneumonia. Apart from these complications a not infrequent dyspnea, the generally good appetite, clean tongue, and maintenance of fair nutrition, and, on the other hand, infrequency of anemia, of marked uremic symptoms, and of a high blood pressure or cardiovascular changes. The short duration of the illness in most cases would explain some of these latter departures from the usual symptoms of other types of nephritis. Severe retinitis or optic neuritis is uncommon, occurring in only three out of 80 cases.

3. **A Method of Flapless Amputation, with Subcutaneous Division of the Bone at a Higher Level.**—W. Sampson Handley suggests a method of amputation

which, while retaining all the important advantages of the guillotine method, will obviate the necessity of a secondary operation. He also believes it is the best way of doing the secondary operation in cases previously submitted to the Kelly method. In a secondary amputation following a Kelly operation it is necessary (*a*) to remove such a length of bone that an adequate covering of soft tissue is provided for what remains. (*b*) To excise the calcified granulations, which do not afford a suitable bed for the spreading epithelium. If calcified granulated tissues are allowed to remain, it is certain that ultimately the skin will be adherent to the end of the bone. (*c*) To do what is necessary with minimum exposure of fresh raw surfaces, since all these cases are necessarily accompanied by sepsis. These requirements are fulfilled by the following procedure: The bone is divided at the selected level by a Gigli saw. Two punctures are made at the end of the bone at the outer side of the limb, separated by about one-third of its circumference. Each of these punctures is situated four inches above the end of the stump. Through one of them a curved pair of forceps is introduced closed, and is insinuated round the bone until it is able to seize the end of the Gigli saw introduced through the other puncture. The pair of forceps is then withdrawn, bringing with it the saw. The bone is now divided, care being taken not to rasp the soft tissues. The punctures are made on the side of the limb remote from the main artery, so as to avoid all risk of injury to the large vessels by the action of the saw. The end of the bone is now seized by lion forceps and with the aid of a periosteal elevator is easily separated from the soft tissues and removed. It only remains to excise the layer of calcified granulated tissue and to insert one or two sutures, making ample provision for drainage. In patients exhausted by long-continued suppuration it may even be advisable to do this little operation in two stages. The first stage is the subcutaneous division of the bone at the selected level. This operation should run an aseptic course. In a few days the isolated distal end of the bone can be removed with a minimum risk of osteomyelitis in the proximal end. This method has been successfully employed as a primary operation on several occasions and may be used to replace the guillotine operation except in cases where extreme rapidity is required.

5. **Dakin's "Dichloramine-T" in the Treatment of the Wounds of War.**—Joshua E. Sweet reports on his experience in the treatment of some 80 patients with Dakin's "dichloramine-T." The new dichloramine solution is made by dissolving the crystals of "dichloramine-T" in chlorinated eucalyptol and then diluting this solution by the addition of chlorinated paraffin oil. It is best applied by an oil spray, an ordinary hard rubber or all-glass atomizer being the most practical method. This method saves the pain of wound dressing and effects an appreciable saving of dressing material. The amount of solution needed is of small bulk. The number of wounds which a surgeon can dress in a given time is far greater than by any other method. The elimination of the Carrel tube simplified the dressing and the problem of the transportation of the wounded. The elimination of the Carrel tube eliminates the time taken by the nurse for the periodic flushing.

La Presse Médicale.

July 26, 1917.

Diagnosis of Tuberculous Otorrhea.—Lermoyer gives a brief historical outline of this subject. In prebacteriological days caries of the petrous bone was set down straightway to tuberculosis. After Koch's discovery the profession was surprised to learn that few or no tubercle bacilli were to be found in otorrheal discharges. From that time we began to hear less and less about tuberculous otorrhea. Even an otorrhea in a consumptive could not be hastily pronounced a tuberculous lesion for statistics came to show that at least 40 per cent. of such otorrheas were nontuberculous. Conversely, a man could have a tuberculous otorrhea and yet not be a consumptive. He could keep his general health and be cured of his ear trouble. His condition often escaped diagnosis, while he himself often dropped out of the control of his otolgist. If we exclude cases which develop in the last stages of consumption not over 10 per cent. of otorrheas involving bone are tuberculous. Twenty per cent. of this 10 per cent. are bilateral. Much the greater incidence of tuberculous otorrhea is in childhood, where it may amount to three-fourths of all cases; while in adults four men are attacked for ever woman. The war has notably increased the frequency of tuberculous otorrhea. Middle ear tuberculosis is a secondary manifestation, *i.e.* other specific lesions must preexist, and one of these may infect the middle ear through the blood, integument, or mucosæ, eustachean infection being the chief cause. Middle ear tuberculosis is ranked as an open lesion in theory, but in practice represents a closed tuberculosis. When actually an open lesion, the way is paved for mixed infection through the perforated drum head. In such cases Koch's bacillus plays second fiddle, and the added pyogenic infection may be expressed as a fulminant process rapidly ending in mastoid abscess, etc.; or it may merely be expressed as an acute exacerbation. In a third class of cases the condition set up is insidious—a sinus phlebitis, intracranial abscess, or meningitis. In diagnosis the first point to determine is whether we are confronted by a true or false otorrhea, true otorrhea always meaning bone involvement. Second, we must ascertain which bone, if any, is involved; if it be the petrous bone, are we dealing with a tuberculous or nontuberculous infection? If the former, the type must be determined—open, abortive, etc. To establish the diagnosis we have factors of probability and factors of certainty. The latter comprise presence of tubercle bacilli in the pus, positive biopsy of vegetations and guinea pig inoculation. The latter is infallible, but requires two months of waiting. The tuberculin test, while efficacious, is dangerous. The presence of tubercle bacilli and a positive biopsy can settle the diagnosis at once, but if they give negative results we cannot feel sure that the case is nontuberculous.

Correspondenz-Blatt für Schweizer Aerzte.

July 28, 1917.

Operation or Irradiation for Cancer of the Uterus?—According to Labhard the radical operation for uterine cancer is now about forty years old, having been initiated by Freund and Czerny with the abdominal and vaginal operation respectively. Their operations culminated in the Wertheim and Schauta techniques. All know that these interventions do not prevent recurrence and recourse was had with avidity to the then new methods of radiation. Within the past three years brilliant end results have been reported from use of the latter along with some discouraging experience. At first wholly inoperable, but latterly operable cases were attacked. Naturally, irradiation may be prophylactic or curative and may be used alone or as accessory to the knife. On account of divisions of opinion, every gynecologist should test the subject thoroughly for himself and be guided by his own experience until such time as a consensus of opinion can be reached. Since January 15 (about two years ago) radium bromide has been used in the Basle clinic, both for prophylaxis and the after-treatment of operated cases, supported by Röntgen radiation. Thirteen operable cases were treated exclusively with rays; 17 operated cases received postoperative irradiation, and 20 inoperable cases (not including 4 recurrences) were treated in the same manner. All of the 54 cases have been controlled to date. The results are probably better than they appear for such unpromising material. The radiated operable cases do not show up very well, for but 2 of the 13 are clinically cured, while 3 are dead. The remaining 8 have not yet improved and some of them are worse. On the other hand, the 17 operated cases with postoperative irradiation show no less than 12 clinical cures. Of the 24 inoperable cases not one has been clinically cured, although 11 patients are still living. The dead in this series number 13. But in all the negative results, radium acted as a true palliative, keeping in check the worst symptoms and alleviating the lot of the patients. This is offset to some extent by untoward by-effects of the radium rays. Six of 37 women treated exclusively with irradiation developed fistulæ. All in

all the author is disappointed in his results and does not understand why they are so much inferior to those of Krönig, Döderlein, Bumm, Klein and others. He is not the only one to feel so and to entertain a certain skepticism as to the suppression of certain data. Do these men mean by "recovery" what he himself implies? What diagnostic criteria are used? It is of course possible that they secure their superior results by superior technique. Suppression of the so-called stimulation effect of too small doses is a very delicate and difficult problem, to which must be added the great differences in the vulnerability of cancer cells in individual cases. Experience of operators also undergoes changes in respect to the relative value and harm of Röntgen rays and radium.

Gazzetta degli Ospedale e delle Cliniche.

August 3, 1917.

Two Cases of Mesoaortitis with Aortic Insufficiency of Luetic Origin.—Binetti reports two cases of this affection in soldiers, each of whom was aged 37. Both patients also showed evidences of incipient tabes. The Wassermann was positive, but to render the diagnosis of specific aortitis beyond question all other possible causal factors could be eliminated. There was a certain amount of general improvement as a result of calomel injections and potassium iodide. The association of mesoaortitis with cerebrospinal metasyphilis is extremely common, although the author only cites figures for paresis in this connection. Naturally the diagnosis in these cases does not have the certainty of autopsy finds (especially microscopic). One of the case reports is as follows: Patient of good stock and antecedents contracted syphilis at 20, and after a year never presented any symptoms of this affection, but was troubled off and on with bronchitis. For some years past he had complained of dizziness, throbbing in the head, dyspnea on exertion, palpitation, and slight edema of the feet toward evening. He served in the army for 3 months before he was interned for bronchitis and declared unfit for military duty. Upon examination was found to present general micropolyadenitis. Careful examination of the chest then revealed the presence of a cardiac lesion. There was hypertrophy of the left ventricle, a Flint murmur (presystolic) at the apex, and accentuation of the second sound. Over the aorta could be heard in addition to a short, mild systolic sound a diastolic murmur, metallic in character and filling the long pause completely. This was most audible over the base of the sternum. The *x*-ray showed the enlarged left side and an enlarged, pulsating aorta. Aneurysm could be excluded. Traube's double sound could be heard over the carotid and axillary arteries; there was no sound over the femoral and no subungual capillary pulse. The neurological examination showed abolished kneejerks and a marked Romberg, with pupils sluggish to light. Comparing the other case with the preceding the aortic focus showed to auscultation a pure first tone, a shrill second sound and diastolic murmur of loud origin, becoming softer and completely filling the pause. It was most audible over the sternum and low down. Over the apex the tones were clean and Flint's murmur absent. On percussion the left ventricle was found enlarged. There is no mention of *x*-ray finds.

The Curve of Mental Labor.—Scelba-Sandesky sums up the results of her original research on this subject in part as follows: She corroborates the finds of others to the effect that school fatigue need not be feared as long as there is a wise distribution of the school work. The curve of reading can maintain fully the ascending type up to the close of an hour of intense application, while the curves of computation (addition, etc.) show a tendency to decline from the outset. These two types of curve are therefore antagonistic. The oscillations in the curves are much more pronounced for reading than for calculation; this depends—at least in part—on the heterogeneity of the material. To account for another factor the author suggests an alternation in the attentive tension in the speech test which does not obtain in the figuring test. The conditions of the research are based approximately on the labors of Maccagno and de Sanctis in Italy and Kraepelin and Ebbinghaus in Germany, in regard to mental fatigue in general.

Colloid Complexes and Their Importance in Biology, Pathology, etc. — Scala concludes that adsorption, or better, the formation of colloid complexes is physiochemical in nature (not merely physical). In the formation of complexes between colloids and electrolytes there is always a liberation of acids and bases. In living organisms, which are formed chiefly of colloids, there is a continuous tempestuous movement of complexes and the liberation of acids and bases is normal within certain conditions, but if it becomes irregular the reactive properties of the colloids are disturbed and a temporary or permanent pathological state is produced. Mineral substances ingested with the food play an extensive rôle in the production of such deviate or abnormal conditions; for the colloid substances in the living organism, chemically inert, develop ionic properties and are then able to form combinations. The inconstancy of the mineral matter content explains the great diversity of behavior in the colloid reactions. The mineral matter in our drinking water shows a greater degree of constancy and contains both saline and colloid complexes in much variety which have physiological properties, not due merely to those of the constituent elements. The author believes that as soon as we understand the relationship between mineral alimentation and maintenance of physiological equilibrium, light will be thrown on the nature of many diseases.

The Psychasthenic.—Sánchez-Herrero asks of this type of individual, "Is he abulic?" and answers that hypobulic is the better term. His volition lacks the element of intensity, he is not dynamogenic, has no executive ability, is incapable of prompt action, must deliberate, is changeable and vacillating, cannot come to a conclusion, and remains in a state of inertia. These subjects are represented in Murger's Bohemians, in coffee house politicians who would reform the country by useless talk while incapable of sustained labor in their proper spheres of activity. Their mental sufferings cannot be transmitted into energy and their output of actual effort is small. They are victims of inhibitions, are pessimistic and egocentric, hyperesthetic, out of touch with the external world, akin to the hypochondriac. In contemplating the endocosm they lose sight completely of the idea of finality. Thomas à Kempis said that all doubts should be referred to God as to the final object of life, the Omega as well as the Alpha. In his intellectual myopia the psychasthenic fails to grasp this solution. Egotism is the only delight of the psychasthenic and at the same time the source of all his misery.

Autobiography of Ramon y Cajal. — Cortezo writes apropos of the second volume of an autobiographical work, "Recuerdos de mi vida," by Spain's foremost medical citizen, whose name heads the list of presidents of the First National Medical Congress of Spain to be held next spring. The publication, through the eminence of the author and his superior literary ability, will doubtless become a classic in the national literature. Through its pages the author stands forth as a great psychologist as well as an illustrious scientist. It is through the former quality that he has loomed up as a teacher par excellence in the branches of science which he has made his own. But he could not have become the national figure that he is as a mere scientist and thinker. Behind these are his personality, which explains his participation in all activities which are national in scope and his unselfish character. Cortezo appends the author's preface, which is dated June, 1917, and seems to suggest his indebtedness to Taine, who is generally acclaimed as the pioneer of modern psychology as distinct from metaphysics. Like most great men, Ramon y Cajal had an inauspicious beginning, and his life represents a series of obstacles successively overcome, which naturally makes his narrative one of unusual interest. He began his medical career as an army surgeon in Cuba.

Book Reviews.

THE NEW SYSTEM OF GYNECOLOGY. Edited by THOMAS WATTS EDEN, M.D., F.R.C.S.E., F.R.C.P., Temp. Major R.A.M.C., Vice-president of Section of Obstetrics and Gynecology of Royal Society of Medicine, Obstetric Physician Charing Cross Hospital, Surgeon Chelsea Hospital for Women, and CUTHBERT LOCKYER, M.D., B.S., F.R.C.S., F.R.C.P., Vice-president of Section of Obstetrics and Gynecology of Royal Society of Medicine, Obstetric Physician to Out-Patients Charing Cross Hospital, Surgeon to In-Patients Samaritan Free Hospital for Women. In three volumes, with numerous illustrations in color and in black and white. Vol. I, 761 pages, with 288 illustrations; Vol. II, 875 pages, with 443 illustrations; Vol. III, 871 pages, with 329 illustrations. Price for the three volumes, $36.00. London and New York: The Macmillan Company. 1917.

THIS is an excellent work and one with whose value the reader becomes more and more impressed with each hour of study. This estimate does not at all coincide with the reviewer's early impressions; for upon merely reading here and there one occasionally gets the impression that a subject is only indifferently covered. This is due to the fact that in some cases various phases of a subject have been split up among several authors and sometimes the reader must look through chapters in one, two, or even all three volumes before he learns all that the work has to offer on the subject.

There are fifty contributing authors, most of whom are men of international reputation, and in this list we find the names of two American gynecologists, H. Franklin Martin of Chicago, who contributes the section on after treatment of gynecological operations, and Howard C. Taylor of New York, who contributes that on vaginal celiotomy. The scope of the work is somewhat wider than the title would indicate; for the editors have felt that certain fields not ordinarily considered as belonging to the gynecologist should come within his domain. Thus we find sections on diseases of the breast, the vermiform appendix, methods of examination of the urethra and bladder, infections of the urinary tract, hernia in women, and diseases of the rectum; while there is a comprehensive chapter on intestinal surgery and one each on radium and Roentgen rays in gynecological surgery.

Space permits but little reference to individual authors' articles. The description of the development of the female genitourinary apparatus is exceptionally lucid, making the genesis of congenital anomalies unusually clear. Although we still have much to learn regarding the physiology and interrelation of the endocrine glands, the subject is in hardly so hazy a state as one would gather from reading the section entitled "The corelation of the internal secretory organs with the function of reproduction." In the chapter on methods of examination the attitude of the author regarding the examination of girls and unmarried women is inconsistent; for in one place he says: "The inability to refer a specific symptom or symptoms to any particular organ is due rather to want of acumen on the part of the examiner or to a deficiency in diagnostic methods," and in another he says: "Needless to say, no local examination should be made upon girls or unmarried women in the absence of urgent pelvic symptoms directly calling for such examination." If the author feels that each individual symptom should be tagged with an etiological label he certainly should not expect the gynecologist to wait until the symptoms become "urgent" before resorting to examination in all except his married patients. Much unnecessary mental and physical suffering has been caused by such diffidence and delay in making proper examinations of unmarried women and young girls; and it is high time the profession realized this point and acted accordingly. The dangers of excising portions of cervical tumors and waiting days for a report before proceeding to radical extirpation are not mentioned, and sufficient stress is not laid on this point in the section on breast tumors. The chapter on ectopic pregnancy is a strong one and contains many valuable suggestions, among which is that of compressing the abdominal aorta when attempting to remove a diffusely attached placenta. The more frequent pathological conditions affecting the genital apparatus are well covered by the various authors, and we find many new suggestions, especially as regards operative technique, that should be most helpful. The chapter entitled Associated Nervous Diseases should be somewhat more exhaustive. The descriptions of pathology are excellent, especially in the second volume, and but little fault can be found with the treatment and technique suggested. We fail to see the advantage of the modification of the classical technique of the Gilliam operation as employed by the author of the chapter on backward displacements of the uterus; while the author of the chapter on prolapse seems unduly exercised in mind over the interposition operation which, admittedly, has its faults but seems distinctly advantageous occasionally. In the chapters devoted mainly to operative technique we find the usual operations well described and illustrated.

The books are well bound, the type is large and clear. there are relatively few typographical errors for a first edition, and the numerous illustrations are usually excellent. The work forms a really valuable addition to gynecological literature.

THE NATION'S HEALTH. The Stamping Out of Venereal Disease. By Sir MALCOLM MORRIS, K.C.V.O., Member of the Royal Commission on Venereal Diseases, etc. Price, $1.25. New York: Funk & Wagnalls Company.

THIS book, written for the laity, especially legislators, contains nothing new for the medical man who is actively interested in the subject. Members of the profession who are unfamiliar with the details of the problems involved could profit from a study of the book, which, however, is written for the British layman, who is much more conservative in his ideas of personal liberty than our own public. We regret to note, in passing, that Sir Malcolm has succumbed to Bloch's arguments in favor of the American origin of syphilis. So far as we know, not a single medical scholar has been won over to this belief through Bloch's book. The historical method of interpretation of old texts has very largely been displayed by the study of original contemporaneous records of every sort, and these are quite silent on the subject of a death dealing pandemic of syphilis after the discovery of America.

THE ELEMENTS OF THE SCIENCE OF NUTRITION. By GRAHAM LUSK, Ph.D., Sc.D., F.R.S. (Edin.), Professor of Physiology at Cornell Medical School, New York. Third Edition. Price, $4.50 net. Philadelphia and London: W. B. Saunders Company, 1917.

AT the conclusion of the preface to this edition the author states "that he has no intention of again revising this book. In another decade the development of scientific knowledge will probably permit the formulation of the subject from the standpoint of physical chemistry." Until that time arrives, and for the immediate present, it may be said that the third revised and enlarged edition of this book connotes our knowledge to date in a very readable form. While the subject matter is of a highly scientific character and on this account may appeal more to those particularly interested in the science of nutrition, at the same time the book deals with so many fundamental problems pertaining to body metabolism in health and disease that it cannot fail to be of distinct value to anyone interested along this line. Such timely subjects as a normal diet, the food requirement during the period of growth, metabolism in diabetes, nephritis, cardiac disease, etc., the influence of drugs upon metabolism, represent some of the practical considerations met with.

In the introduction the author gives many interesting details regarding the studies and experiments of the pioneers in the science of nutrition, such as Pettenkofer and Voit, and shows how certain basic deductions made by these and other early investigators paved the way for the great advances that have been made in recent years. Probably one of the most important chapters is the concluding one on "Food Economics." We cannot do better than quote Professor Lusk on this important topic. Speaking of the probability of food shortage in the United States, he says: "This can be remedied by increasing the number of milch cows and by reducing the live stock raised for meat. . . . It is quite certain that meat in the quantity it is consumed today is entirely unnecessary, and it is susceptible of scientific proof that mechanical work is more efficiently and economically derived from carbohydrate food than from meat."

Public Health Reports.

REPORT ON THE MEDICAL ORGANIZATION OF THE POLICE DEPARTMENT OF NEW YORK CITY BY THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.*

At the request of Mr. Arthur Woods, Police Commissioner of New York City, the Public Health Committee of the New York Academy of Medicine has undertaken a study of the organization and work of the medical service of the Police Department with a view of suggesting to the Commissioner what steps might be taken to increase the usefulness and efficiency of the service. In this study the committee has had the cordial cooperation of Dr. Edward T. Higgins, Chief Surgeon, and of Mr. E. V. O'Daniel, the Fourth Deputy Commissioner, as well as of other members of the Department. The committee was accorded access to all the records of the service and freedom to interview anyone connected with the force. The reports and statistics of the Medical Division have been analyzed and tabulated. Several of the surgeons and one ex-surgeon of the Police Department, as well as a number of patrolmen, have been interviewed. The committee desires to commend the spirit in which the investigation has been met by the officers of the Department and the ready cooperation it has had in securing the desired data and explanations.

On the basis of the information and statistics obtained, the committee has prepared the following report which consists of three major parts: Part I—An analysis of the health problem in the Department, and of the organization of the medical work; Part II—Comments and criticisms; and Part III—Suggestions regarding certain changes and remedies, some of immediate application, others of a more radical nature involving reorganization and possibly requiring changes in the Charter provisions before they can be put into operation.

Part I—The Health Problem in the Police Department.

1. **Statement of the Problem.**—The nature of police work exposes the members of the force to certain hazards and accidents which result in injuries and disabilities. The discharge of police duty involves an irregularity in the hours of work and a consequent irregularity in the mode of life. It entails frequent and prolonged exposure to inclement weather in the winter months and to heat in the summer, and at times demands a considerable amount of overwork. A large measure of illness and disability in the Police force is unavoidable, while a certain amount is preventable. One of the tasks of organization is to eliminate all the preventable disability and to keep the force in a condition of maximum efficiency. A reduction in the sick rate of the Police force is equivalent to an increase in the amount of police service available. Toward the accomplishment of this end the Department maintains a medical corps whose two chief duties are: (1) To certify to every case of illness with a view of determining the fitness of the patrolmen for duty; and (2) To give treatment to every sick or disabled member of the force in order to restore him as quickly as possible to his post.

The treatment of disabled policemen was added definitely to the duties of the Medical Division only three years ago; prior to that time it was not required, although some of the surgeons always have given medical care voluntarily.

2. **Organization of the Medical Service.**—At the present time the medical staff of the Police Department consists of 18 surgeons. One is designated as Chief Surgeon and is assigned to administrative and consultant work, and one devotes his whole time from 9 A. M. until 5 P. M. to the recently organized clinic, opened on October 15, 1916, at Headquarters. The clinic has not as yet been properly equipped, while the average attendance is about 20 patients a day. The remaining 16 surgeons do district work covering the entire city.

The Charter admits the employment of 40 surgeons at a salary of $3,500 a year. The Board of Estimate and Apportionment, through its failure to appropriate the necessary funds, has reduced the number of surgeons to 18.

At the present time there is one district surgeon to every 700 men in the Police Department. The surgeons' districts are large, particularly in the less densely populated boroughs, and are based on the number of patrolmen residing in a certain area, regardless of where they are assigned to duty. The average size of a surgeon's district in Manhattan is over 5 square miles, in Brooklyn 12½, in the Bronx 13¾, in Queens 30, and in Richmond 57 or the whole Borough. The surgeon in charge of Richmond has also a section in Manhattan between 86th and 110th Streets on the west side.

The duties of the surgeons can be divided into two classes: (A) Regular, and (B) Incidental.

A. The regular duties consist in examination of applicants for admission to the police force, reexamination of applicants at the end of six months' probation period, examination of patrolmen for pensions, examination of patrolmen reported ill or injured, treatment of ill and injured patrolmen, and examination of applicants for reinstatement. These latter examinations are made by a committee of three surgeons. The statistics of examinations made in 1916 are as follows:

Examinations for reinstatement	292
Reexaminations at end of probation period	228
Examinations as to fitness for police service	216
Examinations for retirement	53

The examinations for retirement are made by a committee of five surgeons.

The surgeons are expected to be regular in their attendance at the meetings of the Board of Surgeons, called twice every month. They are also called upon to give lectures to patrolmen in the Training School on first aid to the injured. Last year 30 such lectures were given, though not a single lecture was given on personal hygiene for the men themselves.

B. The incidental duties of the surgeons consist in attendance at large fires, explosions or other major calamities, in attendance at parades—at the 5 large parades in 1915 on an average 12 surgeons were on duty at each parade—attendance at certain medico-legal autopsies at the request of the Detective Bureau and also in cases of suspected rape, and attendance at the trial court in cases of malingering patrolmen brought up on charges by the surgeons. There were about 100 such cases in 1916 and the average time spent by the surgeons at each trial was about 3 hours. About 150 emergency visits are made to precinct station houses in a year; these include calls to station houses in cases of arrest of intoxicated chauffeurs. Last year 12 surgeons were required to be in attendance at the Police Training Camp at Fort Wadsworth for a period of 2 weeks each.

In case of illness of a surgeon or during vacation period, his work is apportioned among his colleagues, and the size of their districts necessarily is increased thereby.

At the present time the surgeons have no definite hours of work. There are no Charter provisions as to the time to be given by the surgeons in the performance of Department duties, nor are there any Departmental regulations to that effect. According to the statement of the Police surgeons, they give on a average 7 hours per day for 7 days per week throughout the entire 52 weeks in the year. This would give approximately 40 minutes per patient, as the average number of visits per day per surgeon is 10.9, as reported by the Police

*Committee: Charles Loomis Dana, M.D., Chairman; James Alexander Miller, M.D., Secretary; Nathan E. Brill, M.D.; Robert J. Carlisle M.D.; Floyd M. Crandall, M.D.; Lewis Fox Frissell, M.D.; Arpad G. Gerster, M.D.; John A. Hartwell, M.D.; Thomas W. Hastings, M.D.; L. Emmett Holt, M.D.; Abraham Jacobi, M.D.; Howard Lilienthal, M.D.; Bernard Sachs, M.D.; Thomas W. Salmon, M.D.; Frederick E. Sondern, M.D.; W. Gilman Thompson, M.D.; Frederick Tilney, M.D.; Philip Van Ingen, M.D.; Karl M. Vogel, M.D.; George B. Wallace, M.D.; E. H. Lewinski-Corwin, Ph.D., Executive Secretary.

Department. Allowing the time spent in transit to and from the patient this seems a high average, particularly when one takes into consideration the fact that only one-third of the calls are home visits, the remainder being office visits at which full physical examinations are seldom given.

The total number of visits recorded for 1916 was over 63,000, of which 53,869 were visits to members of the force actually on sick report. The difference between these figures represents about 9,000 extra calls which were made in the treatment of convalescents after return to duty, and of sick patrolmen who, not wishing to suffer a reduction in pay because of illness, take their vacation during the time of illness. These cases do not appear on the sick list, but the patients nevertheless are entitled to treatment. The extra calls also include examinations made by the surgeons at their semimonthly meetings and the cases referred by one surgeon to another, who may be a specialist in a certain branch of medicine, for confirmation of doubtful diagnosis. No exact classification of these calls is available.

Of the 18 surgeons 2 are genito-urinary specialists, 2 are nose and throat specialists, 1 is a surgeon, 1 is a gynecologist, and 1 is a pediatrician. The others are general practitioners.

An analysis of the dates of appointment shows that one of the surgeons was appointed 30 years ago, one was appointed 29 years ago, and two were appointed 24 years ago. The remaining appointments have been made since 1900—one in 1900, two in 1902, one in 1903, one in 1904, three in 1907, two in 1909, two in 1910, one in 1911, and one in 1912.

The surgeons are required to send in daily reports on which are specified all the employees of the Department under their care, the names of the patients seen that day being indicated by a special mark. In addition, the police surgeons are required to send in daily slips for every patient who has been referred to them as sick. On this slip the diagnosis is recorded. No history cards are made out nor are they required.

All the surgeons of the department are of equal rank. The Chief Surgeon is designated by the Commissioner and serves at the pleasure of the Commissioner. He has authority over the other surgeons, which, because of the insecurity of the office, he may not care to exercise. Due to the indefinite tenure of the office of Chief Surgeon, the administrative discipline necessarily has been lax.

Surgeons, as other employees of the Department, are entitled to pension after 25 years of service if they have reached the age of 55 years. According to the present rules anyone leaving the Department before he is legally entitled to a pension does not receive a surrender value of the contributions made during the preceding years. This pension system may act as a deterrent to surgeons who, because of a large practice which they may have built up or because of other pressing duties and obligations, would leave the service if they received a surrender value commensurate with the amounts contributed and based on the length of service.

The powers of the Commissioner with reference to the surgeons are the same as those with reference to the other members of the Department, and he may promulgate such rules as he thinks best. He may require full time service, and residence within or near the District to which the surgeon is assigned. He may discipline by suspension, fine or dismissal for any misconduct, infraction of rules, or neglect of duty. A surgeon may be brought up on charges. The surgeon against whom charges are preferred has legal right to a hearing before the Commissioner, the right of employing counsel, and the right of having the case reviewed by a court. The dismissed surgeon may seek court reinstatement, as was done by one surgeon who was suspended because of insufficient budget appropriations to pay all the surgeons. The court reinstated the surgeon, holding that the Board of Estimate and Apportionment did not have the authority to reduce the number of surgeons in this manner.

3. Statistics of the Police Force, and Rules Governing Sick Leave and Pensions.—There are about 11,000 employees in the Police Department. 10,592 are in the uniformed force, and 10 per cent. of these are in the higher ranks, *i. e.* holding positions as captains, lieutenants, sergeants and inspectors, at salaries graded according to rank.

The age distribution of the police force cannot be obtained as of the present time, but the pension report made by the Commissioner of Accounts early in 1913 showed that the median age was 35 years. The age distribution has probably changed slightly since 1913 and presumably has raised the median to a younger age group, as quite a considerable number of new patrolmen were appointed since the early part of 1913 and a large number of older men were pensioned during Commissioner Waldo's administration.

The committee has been unable to ascertain definitely the marital status of the police force. The estimates place the number of married men as being over 90 per cent. of the force.

With the exception of the Traffic Squad, which works daily for eight hours and for an hour or two in the theatre district at night, the majority of the force is divided into three platoons, each platoon working eight successive hours. Every tenth day the tour begins at a different hour. For instance, if a platoon should start on a certain day to work at 12 midnight they would work until 8 A. M. for nine days; then, on the tenth day they would begin to work at 4 P. M. and work until 12 midnight for nine days; then they would begin to work at 8 A. M. and work until 4 P. M. for another nine days.

Each platoon consists of three squads, each squad doing reserve duty three days in every nine days. When on reserve duty the patrolman has four hours of leave after his regular tour; he then goes to the precinct station house for eight hours of reserve duty, during which he may sleep, as beds are provided at the station houses; and then he has four hours more of leave, after which he goes back on regular patrol duty. The chief surgeon stated that the four hours of leave is purely nominal, as the officer may have duties to perform at court or elsewhere.

The short hours of leave in many instances prevent the policeman from going home. He often lives a long distance from the precinct station. For this reason, and also because of the inconvenience to his family of preparing meals at irregular hours, he often secures his meals at a nearby restaurant.

The Charter of the City of New York provides for the manner and conditions under which members of the force may be dropped because of physical disability. There are but four ways in which the members of the force can sever their relation with the Police Department: By death, resignation, dismissal (Section 300), or retirement (Section 354, pp. 3 and 4, and Section 355). A policeman may be retired when he reaches the age of 55 years if he has been in service for 25 years. The Commissioner may retire a member of the force when he reaches the age of 60 years. Members of the force suffering from permanent disability may be retired only after 10 years of service, with a pension equal to one-fourth of their annual salary. Should the disability occur before the expiration of 10 years of service, the disabled patrolman cannot be retired but must be carried on the sick list and given half pay. In other words, if a man should become disabled during the first year of service, he would be granted nine years of sick leave on half salary. At present there are 23 patrolmen unable to do full duty who must be carried on the pay roll of the Department. The disease disabilities and operations which bar them from active service are as follows:

Tuberculosis	8
Pulmonary emphysema	1
Blindness	1
Neurasthenia	1
Epilepsy	1
Flat feet	1
Diabetes	1
Chronic rheumatism	1
Chronic Bright's disease	1
Gastroenterostomy	2
Hemiplegia	2
Amputation of thigh	1
Spondylitis	1
Deformity of leg, following fracture	1

Some of the patrolmen whose disabilities are prolonged but who can be of some service to the Department are assigned to light duties, such as watching raided premises, for example.

When the policeman becomes ill he, or someone for him, is required immediately to notify the precinct station house in person. A statement of his condition is not required, but the lieutenant inquires whether the patient will be able to go to see the surgeon or whether the surgeon should be sent to him. In the latter case a notice is sent to the surgeon by messenger, but the surgeon has no way of determining whether or not the case really requires immediate attention.

A policeman reporting ill is automatically admitted to sick leave and is given half pay, except in cases of injury received during the actual performance of police duty and by reason of the same, when he receives full pay. He is continued on the sick report under charge of his district surgeon until entirely recovered and returned to duty.

4. **Morbidity Statistics.**—The morbidity statistics for 1916 are as follows:

Total number of admissions to sick report, including readmissions.	8,316
Total number of days lost because of illness	76,101½
Total number of days lost because of injury	25,732½
Average number of days lost per sick patrolman	9.1
Average number of days lost per injured patrolman	14.0

The average percentage of time lost per annum on account of illness or other disability was as follows:

1914	2.29 per cent of the total time of expected service.
1915	2.16 per cent of the total time of expected service.
1916	2.54 per cent of the total time of expected service.

The rate is lower than that of London, England, which in 1914 was somewhat over 3.0 per cent.

The following is the distribution of days lost by months for 1915 and 1916. In 1916 the number of days lost was larger, month for month, than in 1915 with the exception of April.

1915		1916	
January	8,019	January	10,847
February	7,211	February	9,026
March	7,951	March	10,045
April	7,956	April	8,167
May	6,463	May	7,445
June	6,093	June	7,032
July	6,768	July	7,181½
August	6,643	August	8,294
September	6,464	September	8,244
October	6,601	October	9,143½
November	6,760	November	7,513½
December	7,940	December	8,895½

The large amount of sickness in January, February and March of 1916 was attributed to the epidemic of grippe and influenza; and the high incidence of sickness in the summer of 1916 was due in a measure to the strain put upon the policemen by exigencies of the traffic strike.

Comparative Statistics.—An attempt was made to secure information bearing on the sickness rate of policemen in other American cities, and letters of inquiry were sent to a number of police departments. Replies have been received from four cities: Boston, St. Louis, Philadelphia, and Chicago.

In Boston sick leave is counted, as in New York, from the first day of illness. In 1916 the total number of days lost because of illness was 8,006 in a force of 1,618, or 4.9 days per man. The total time lost on account of illness was 1.4 per cent. The total number of days lost because of injuries was 2,744, or 1.7 per patrolman in the year 1916. The loss of time of absentees from duty on account of injuries was one-half of one per cent. of the required total time of service. The total percentage loss of time on account of both sickness and injury was 2.2, which is lower than our city police rate. It may be noted that the Boston Police Department does not employ any surgeons.

The health statistics of the St. Louis police force, which the committee obtained, allow of only a few comparisons. The total loss of time due to sickness disability was 10,739 days in 1916. The total force of the city is 1,661 men. The average number of days lost because of illness per member of the force was 6.4. The annual rate of illness, as reported, was 1.6 per cent. in 1916. The St. Louis Police Department employs four surgeons on a basis exactly the same as that obtaining in New York City. The chief surgeon gets a salary of $3,000, the assistant surgeons get $1,200. The surgeons may be called upon at any time to attend to the police department calls irrespective of the claims of private practice. The surgeons in St. Louis are chiefly disciplinary officers, but they attend sick members of the force who desire their services.

In Philadelphia the police department employs one surgeon at $4,000, who gives full time to the work. In addition, the department has 41 district surgeons who work on a fee basis. Sick patrolmen are not treated by the police surgeons except when injured in the performance of duty. There are no detailed statistics available concerning the Philadelphia force, which numbered 3,928 in 1916. On the average, 354 were admitted to sick report monthly, and 10.4 days was the average time lost on account of illness per man per annum.

In Chicago the police surgeons perform ambulance work and give only first aid to the members of the force, similar to that given to any other injured person. There are no detailed medical statistics available for the police force. In 1916 about 1,300 police officers, in a force of 5,075, were examined for sickness or injury. No other data have been obtained.

The experience of the New York Fire Department is as follows: The uniformed force of the Fire Department is 5,026 and the civilian force is 777, making a total of 5,803. In 1916 the budget provided for a salary of one medical officer at $4,200 and of nine medical inspectors at $3,300. In the Fire Department a man is not admitted to sick report until he has been seen by a surgeon. The surgeon must see the sick fireman within six hours after report is made. The health statistics of the Fire Department are as follows:

	1914	1915
Number of cases of illness	2,129	2,373
Number of cases of injury	836	663
Total number of cases of disability	2,965	3,036
Days lost on account of illness	28,649	38,021
Days lost on account of injury	12,950	12,182
Total days lost	41,599	50,203
Average number of days lost on account of illness	13.4	16.0
Average number of days lost on account of injury	15.5	18.4

The average number of days lost per case of illness, as well as per case of injury, was larger in the Fire Department than in the Police Department, the rate for the latter being 9.1 and the rate for the former being 14.4 in 1916.

The following table brings out certain comparisons:

	1916. New York Police	1916. Boston Police	1916. St. Louis Police	1916. Chicago Police	1916. Phila. Police	1915. New York Fire Dept.
Number of men on force, uniformed	10,592	1,618	1,661	5,075	3,928	5,026
Number reported ill	8,316	..	..	About 1,300 m'nthly	Average of 354	2,373
Number reported injured						663
Total days lost on sickness	76,101½	8,006	..	....	....	38,021
Total days lost on injury	25,732½	2,744	10,739	..	..	12,182
Average number of days lost per sick member of force	9.1	..	..	..	..	16.0
Average number of days lost per injured member of force	14 0	..	....	..	....	18.4
Average total time of disability per disabled member of force	12 2				10 4	16.5
Average duration of sickness per member of the force in days		4 9		..	..	7.5
Average duration of injury per member of the force in days		1.7		..	....	2.4
Average of total time of disability per member of the force	9 6	6.6	6.4		..	9.9
Average percentage of time lost on account of illness or other disability	2.54	2.2	1.6	....	....	..

In the entire New York police force the total number of cases of disease disability in 1916 was 10,156; of these, the most important diseases, numerically considered, are as follows:

Diseases of the digestive system.	2,592
Infectious diseases	2,584
Of which there were 1,420 cases of influenza	
580 cases of acute articular rheumatism	
58 cases of tuberculosis, and	
29 cases of lobar pneumonia	
Diseases of the respiratory system	1,312
Diseases of the nervous system	959

It is interesting to note that in the detailed medical report there were recorded only 26 cases of alcoholic poisoning, 29 of lobar pneumonia and 155 classified as diseases of the reproductive and urinary systems. A striking feature of the report appears in the fact that while during the years 1914, 1915 and 1916 the number of diseases of the digestive system remained practically the same, there was a marked increase in the number of diseases classified as of the nervous system, 444 such cases being reported in 1914 as against 959 in 1916. The genito-urinary cases remained substantially the same in number. The remaining cases included in the number of total disabilities were varied in nature and for the most part of ordinary character, such as would naturally occur in any large group of 10,000 or so men.

The number of patrolmen off duty daily on account of disabilities varies with the season of the year. It is larger in the winter months than during the summer. On February 2, 1917, there were 390 men of the uniformed force on the sick list, of whom 15 were in hospitals. The distribution by hospitals and boroughs was as follows:

Manhattan Hospitals.

	Precinct.	Hospital.	Diagnosis.	Condition.
1	23	Bellevue	Fracture of knee	Healing
2	21	Bellevue	Pott's fracture	Complicated
3	144	Polyclinic	Appendectomy	Healing
4	16	St. Vincent's	Pneumonia	Stationary
5	23	New York	Scalp wound	Stationary
6	13	Seton	Pulmonary tuberculosis	Stationary
7	63	Hahnemann	Hernia, operated	Doing well
		Bronx Hospitals.		
8	68	St. Francis	Hernia	Improving
9	T.D.	Lincoln	Exostosis metatarsal bone, operation	Stationary
		Brooklyn Hospitals.		
10	145	Kings County	Varicose veins	Improving
11	D.B.	Prospect Heights	Gastric ulcer	Improving
12	174	Coney Island	Fracture of femur	Stationary
13	169	Coney Island	Hernia	Stationary
14	170	St. Peter's	Meningitis	Doing well
		Queens Hospital.		
15	277	St. John's	Lumbago	Stationary

The Police Department does very little in the way of disease prevention among its employees. In recent years the only approach to preventive work has been the publication of a leaflet "How to Keep Well," published on October 1, 1915, for distribution among the force, and the occasional articles on health in the Monthly Bulletin of the Department. In May, 1915, there was an article on digestion; in June there was a short article on vacation typhoid; and in July the Bulletin was devoted entirely to an article on foot troubles, their cause and prevention, prepared by the chief surgeon in co-operation with four other surgeons. In a later Bulletin there was a short article by Dr. Higgins on the influence of fresh air on health.

Systematic lectures on personal hygiene and disease prevention are not given, and the Department does not require periodic physical examination of the force.

5. Mortality Statistics.—During the year 1916, 79 patrolmen, or seven-tenths of one per cent. of the active uniformed force, died. The causes of death are summarized as follows:

Infectious diseases:	
Pneumonia	12
Typhoid	1
Tuberculosis, pulmonary	5
Urinary system:	
Nephritis, chronic	10
Diseases of metabolism:	
Diabetes mellitus	3
Diseases of digestive system:	
Liver and gall-bladder	4
Stomach and intestine	4
Circulatory system:	
Cardiac disease	11
Disease of brain and nervous system	7
Malignant tumors:	
Carcinoma	6
Osteosarcoma	2
Injuries:	
Extreme multiple injuries	3
Fracture of the skull	3
Pistol shot wounds	8

Part II—Comments and Criticisms.

1. Medical and Preventive Work.—The rules governing the duties of surgeons with reference to treatment of sick members of the force never have been defined clearly. Some of the surgeons always have given medical care to sick policemen voluntarily, while others have not considered it their duty. In order to determine in a general way the attitude of the patrolmen regarding the medical care they receive, a number of them were asked by the committee to express their opinion on the subject. The impression appears to be quite prevalent among the members of the force that there does not exist any close relationship with the surgical division. One man stated, for instance, that it was the impression among his friends on the force that the surgeons are glad to pass them on to outside physicians and are rather bored to treat the men. Another stated that much illness might be prevented if the patrolmen felt more free to go to the surgeons for early preventive instruction before they became seriously ill; in other words, to go to them at times when not actually applying for sick leave. Most of the men agree in attributing their digestive disorders in part to the necessary irregularities in their mode of life, particularly with reference to meal hours and sleep, and in part to their own indiscretions in diet, many of them eating wrong kinds of food, drinking inordinate quantities of coffee, etc. A few of the men attributed such digestive disorders to excessive alcoholic indulgence.

According to the understanding of the committee, at the present time the medical service of the department consists of diagnosis and treatment of disease, and disciplinary control of malingering. It is the opinion of the committee that in order to perform these two functions satisfactorily, *i.e.*, to have a prompt and rigid disciplinary control and to give to sick members of the force as good treatment as is expected in private practice, a larger number of surgeons than are at present at the disposal of the department would be necessary. This larger number would be 40 per cent. greater than at present. But the committee is of the opinion that since the conditions of service in the Police Department are entirely different from those prevailing in the army, an attempt to exercise full control over the health of the force by the department is impractical and always impossible of full attainment, the first reason being that it would require hospital facilities, and the second being that it would interfere with the constitutional rights of the men to such treatment as they considered best for themselves. Treatment, even if exercised through additional surgeons, would necessarily apply only to a part of the force, although presumably a majority of the men might avail themselves of the medical services offered.

It is the feeling of the committee that the interests of the department would be served to a greater extent if the medical service were limited to diagnosis and prevention of disease, and disciplinary control. Preventive work has been almost entirely neglected, no instruction in personal hygiene being given. All the medical lectures given in the Training School were on first aid to the injured. The department does not require periodic (annual) physical examinations of the force. It is the opinion of the committee that the institution of such examinations is desirable and that it would result in a decrease in the sickness rate. This has been the general experience wherever periodic physical examinations have been carried on. In the Milwaukee Street Railway service, for example, the sickness rate has been decreased from nine to something over four days per annum since periodic physical examinations have been made. In the Health Department of New York City, in spite of the constant contact which a large percentage of the force has with infectious diseases, and in spite of the considerable

number of clerks in the department, whose work is indoor and sedentary, absence on account of illness is less than in the Police Department, and was considerably decreased in the two years following routine annual examinations.

The question was raised whether a system of periodic examinations which will inevitably lead to the discovery of a variety of chronic conditions would not result in an increase of malingering and in making hypochondriacs of some of the men, who would be apprised of their condition and warned against certain things which their police duties might demand of them. It is the opinion of the committee that these are exaggerated fears and that the system, if carried out with proper judgment, would bring about a considerable reduction of preventable disease. Periodic physical examination has been accepted as one of the fundamentals of modern preventive medicine.

2. Organization of the Medical Service.—The present administrative organization of the Medical Division of the Police Department is defective. There is no concentration of authority. The chief surgeon is appointed by the commissioner and serves at the pleasure of the commissioner. With a change in administration he may be returned to district work. Under the present circumstances he may not care to exercise rigid control over the other surgeons, any one of whom in time may become his chief. His position does not carry with it particular prestige or a higher compensation, and his duties are chiefly clerical. The committee believes that an organization with a gradation of ranks and salaries would be more adaptable to administrative efficiency and would create more of a spirit of emulation than is at present possible with all the surgeons of the same rank and receiving the same salary from the time of entrance into the service until the day they leave it. Such a graded organization would comprise (1) a chief surgeon, (2) a number of district surgeons, (3) a number of assistant surgeons, and (4) a number of medical inspectors.

3. Admission to Sick Report.—The present method of reporting illness by the members of the force is defective, as it frequently imposes unnecessary hardships on the surgeons and affords opportunity for malingering on the part of the men. According to the present rules of the department, when a man reports ill either in person or by a responsible messenger, he is admitted to sick leave immediately. He is merely asked whether he will go to see the surgeon or whether the surgeon should be sent to see him at his home. If he should report sick late at night and declare that he would see the surgeon next morning, it would be very difficult for the surgeon to determine whether an alleged acute headache or stomach disturbance warranted his refusal to perform duty the previous night. If the man reporting ill at night should ask that the surgeon see him at his home, the surgeon is immediately notified by messenger. No report is made of the symptoms of the illness nor whether it is urgent that the patient be seen immediately. The surgeon uses his own judgment. Sometimes he goes to see the case immediately, only to find that the patient is suffering from a trivial ailment or perhaps that in order to relieve a condition he should have brought certain instruments with him.

In the opinion of the committee there should be a change in the method of reporting, which would prevent malingering and would at the same time relieve the surgeons of making unnecessary calls. The procedure in the Fire Department, whereby a man is not admitted to sick leave until he has been seen by a department physician and which provides that the physician must see him within six hours after the report is made, seems preferable to that existing in the Police Department. Instructions should be given to the officers in charge of the precinct station houses to ascertain in a general way the nature of the complaint of the man reporting sick, and convey this information to the surgeon in cases requiring house calls.

4. Medical Records.—The medical records of the Police Department are very inadequate in that they give only a designation of maladies without any additional data concerning the patients, the nature of the disease, the duration of convalescence, and the home conditions surrounding the men under treatment. The form of report is unsatisfactory in that it requires the surgeons to write out daily the names of all the men under their care and to designate by a check mark opposite the names the patients seen during the day. This involves unnecessary labor and renders it impossible, except with the expenditure of a great deal of time, to trace the record of visits to every individual patient. The record keeping could be greatly improved by changes in classification and nomenclature, the introduction of modern forms, and a proper arrangement of the files.

The classification of morbidity statistics should be done carefully, and should follow a recognized nomenclature, such as that of Bellevue Hospital.

5. Sickness Statistics.—In comparing the three groups of diseases—digestive, respiratory, and nervous—in our police force with those in the Boston police force for 1916, one is surprised at the difference in the relative importance of the three groups in the two cities, as seen from the following table:

	New York City		Boston	
		Per Cent		Per Cent
Total cases of disease disability	10,156	100	744	100
Digestive	3,126	30.9	132	17.7
Respiratory, exclusive of influenza	1,399	13.8	357	48.0
Nervous	959	9.4	24	3.2

The digestive disturbances constituted the chief group of ailments in the New York City police force, whereas the respiratory diseases constituted almost one-half of all the illness in the Boston force. Then, too, the prevalence of nervous disorders is three times as great in the New York force as among the patrolmen of Boston.

The committee examined the records of diagnosis in 980 cases reported last year among the New York force, in which diseases of the nervous system were specified. Under this heading there were recorded among the principal ailments the following:

Insomnia	114
Neurasthenia	134
Neuritis	66
Neuralgia	134
Neuralgia of the face	63
Lumbago	169

Many of these cases are recorded as having been under treatment only for one or two days, whereas neurasthenia, if genuine, is a serious ailment of gradual onset and protracted course. It is also difficult to understand why there should be so many cases of insomnia in a selected body of men, which are recorded as having been under treatment only from one to two days. Insomnia, when serious, is usually the outcome of definite disease, worry, strain, etc., and is not ordinarily curable so promptly. If trivial, lasting only one or two nights, it hardly demands consideration and should not be incapacitating.

It should be noted, however, that to a certain extent the occurrence of "insomnia" may be referable to crowded and improperly ventilated sleeping quarters in the station houses, or occasionally to prolonged duty in connection with the control of strikes, or similar work.

Neuralgia and neuritis are conditions which may or may not have serious underlying causes. In some instances these conditions may be due to exposure, fatigue, indigestion, alcoholism, etc. If serious, they are usually symptoms of some underlying ailment, record of which should be made.

The number of cases recorded under the diagnosis of "facial neuralgia" attracts attention. This disease is uncommon among males. It has been noticeably decreased among motormen and chauffeurs, since the wide introduction of windshields. If so many cases occur among the policemen they should have better protection of the face as with mufflers or heavy caps or collars to be worn in severe weather.

The question naturally suggests itself whether a good many of these minor ailments, recorded under "diseases of the nervous system," may not be due to malingering or alcoholism. It is the impression of the committee, however, that with the present esprit de

corps of the force these factors cannot be especially important.

The general comments to be made upon the nature of the diseases reported as observed among the force are as follows: The rate of illness, while not exceptionally high, in all probability might be reduced by as much as 25 per cent. The more serious types of illness, such as pneumonia and appendicitis, are unavoidable and are in no respect more numerous than is to be expected. The minor ailments, however, particularly the digestive and nervous diseases, on cursory examination appear to be excessive, and if any reduction in the morbidity rate is to be obtained it could be brought about through more attention to preventive measures against these groups of ailments. The police surgeons, themselves, for example, on finding a patrolman suffering from insomnia or dyspepsia might investigate in detail the conditions which led to the trouble, to determine whether they are due to such factors as poor sleeping accommodations, improper diet, drinking too much alcohol or coffee, etc. No doubt, in many cases useful instructions could be given to the patrolmen in regard to bettering their home environment or changing their personal habits.

6. Sickness Rates by Districts.—The Committee obtained statistics by months of the number of days lost through illness in each of the sixteen surgeons' districts, and computed the average days of absence per patrolman in each district to determine the variations from one district to another. It appears that the variations are in some instances considerable, from 7.3 days to 13.2 days per patrolman per annum.

The following is the table as computed on the basis of the statistics obtained:

Days of Absence Through Sickness. Comparison of the Sickness Rate in the Different Police Surgeons' Districts in New York City.

District.	Number of Patrolmen in District.	Total Days of Absence.	Average Annual Absence per Patrolman	Number of Permanently Disabled Patrolmen in District
1	572	5541.5	9.7	
2	520	6070	11.7	4
3	581	5533.5	9.5	2
4	608	6020	13.2	
5	591	5786	9.8	3
6	523	4095	7.8	1
7	610	4437	7.3	
8	639	4867	7.6	4
9	613	5508.5	9.0	2
10	581	4579	7.9	
11	612	5941.5	9.7	3
12	515	4724	9.1	
13	540	3694	9.0	
14	598	4859	8.1	1
15	572	5218	9.1	1
16	590	6472	11.0	2
17*	481	3878.5	8.1	
18	437	4014.5	9.4	
19	502	3744	7.5	**

*Since November, 1916, one surgeon has retired, one has died, and one has been assigned to clinic duty. As a result, the number of districts has been decreased from 19 to 16.

**The differences in the district sickness rates are attributed in part to the uneven distribution of hospitals. Policemen when in hospitals come under the supervision of the surgeon in whose district the hospital happens to be located. As the number of policemen in hospitals is not very large at any time, the discrepancies can hardly be explained by this element affecting the rate. The Committee did not have time to make a more detailed study of the causes, but suggests that it would be worth while to determine the causes of these variations.

The distribution of chronic cases carried on the sick roll of the department by surgeons' districts shows that the largest number of chronic patients is not necessarily in the districts showing the highest sick rate. As a matter of fact, in one of the districts where the rate is highest, 13.2, there is not a single chronic case domiciled.

7. Sanitary Conditions of the Precinct Station Houses.—Representatives of the committee visited a number of the station houses with a view of determining their hygienic conditions. The stations appear clean and are kept in as good order as the conditions of the buildings will permit. The more modern buildings afford exceptionally good accommodations with regard to dormitories, lavatories, etc. In several of the older station houses the conditions, owing to the structure of the buildings, are most unsatisfactory. For example, in one station house dormitories, approximately 27 by 28 feet square, contain 25 beds each, besides large lockers which occupy a great deal of room. In these dormitories the beds are so close together that one must walk sidewise to pass between them, and in many instances the heads of the beds were within 8 or 10 inches either of a radiator or a window, conditions which might easily predispose to taking cold. In cold weather the windows are not adequately opened, owing to the proximity of some of the beds to the windows, the occupants of which complain of the cold. The result is that the air becomes very foul after a squad has occupied the dormitory. Arrangements for darkening the windows for the daytime sleepers were in many cases inadequate and out of order. Sleeping under such conditions is neither healthful nor restful.

The beds are comfortable and clean, every effort being made to eradicate vermin.

The clothes lockers are of exceedingly faulty construction. Modern lockers with pressed metal sides are designed to permit free ventilation whereas the lockers in the dormitories of the station houses are ventilated only by one or two narrow slits six inches wide. The result is that when a wet raincoat, wet boots, etc., are placed in the locker the patrolman's underclothing becomes very damp. In some of the lockers towels were shown which were still wet after hanging for 8 or 10 hours. As the police regulations require that all clothing of the men while sleeping should be locked in the lockers, it would seem desirable to have holes bored in the lockers, sufficiently numerous to insure thorough ventilation. The only objection to this would be the possible access afforded to vermin, but this should be controlled in other ways. Lockers should not be in sleeping quarters. The possibility of installing drying rooms is also suggested.

In one of the station houses visited, a dormitory under the roof, into which large beams projected, presented very inadequate ventilation, there being only two-foot windows placed at the floor level, together with skylight windows, the arrangements for opening which were out of order. In general, the bathing facilities, hand basins and toilet closets were found adequate and in fairly good order.

The lounging rooms for the men vary greatly in the different station houses. In one room in which at times as many as 40 men congregate there were only seven chairs. In another room there were no chairs and only exceedingly uncomfortable narrow hardwood benches. It seems a pity that men who must be on their feet so constantly while on duty should not be given comfort in their off hours in the station houses. The newer houses, however, are much more adequately equipped in this regard.

While the present sleeping accommodations may be sufficient for the ordinary reserve force, they are inadequate in cases of emergencies. During the several months of last year when the total force of the department was on reserve call, the accommodations were entirely insufficient and a number of the men had no facilities for sleeping. As a result, some of them reported for sick leave, which was granted in order to enable them to obtain sufficient sleep, and this sick leave was entered as "insomnia." This may account for the unduly large number of cases under this heading, referred to above.

Part III—Recommendations.

A. Of Possible Immediate Application.—1. Establishing a permanent office of Chief Surgeon, with a salary higher than the other surgeons receive, and vesting him with recognized and definite authority over all the employees of the Medical Service.

2. The duties of the Police Surgeons should be limited to the functions of diagnosis and prevention of disease, control, and administration. They should not be permitted to treat patients outside of the clinics, except in emergencies.

3. The clinic at headquarters should be equipped adequately and enlarged, and a dental clinic should be added to it. The latter would do much toward preventing gastrointestinal and "rheumatic" disorders.

The committee recommends also the employment of a chiropodist to attend to the minor foot ailments of the policemen.

The committee suggests also the possibility of establishing such clinics in other boroughs, or what is still better, of making arrangements with the existing dispensary clinics for the utilization of their equipment at certain fixed hours, and that the patients be under the charge of surgeons of the department.

4. Arrangements might be made with the city hospitals, as well as with some of the private hospitals, for special facilities to be provided for the sick members of the force.

A special fund might be created for defraying the expenses incurred in providing accommodations in hospitals.

5. The members of the force should be examined annually by the surgeons, and should receive proper medical and hygienic advice at the time of examination.

With the existing staff of surgeons, the average number of examinations per surgeon will be about two daily.* On the basis of experience in industrial establishments, 20 minutes should be the average time allowed for the examination of each man.

In addition, instructions in hygiene should be given, in the form of specially prepared pamphlets applicable to conditions most commonly encountered in the police force, and given to the men at appropriate times when they will be most appreciated.

6. There should be a change in the procedure of admission to sick report, to make it correspond with that of the Fire Department of New York City. A man should not be admitted to sick report until he has been pronounced ill by a police surgeon who shall see him within a few hours after the man had reported sick.

For a better correlation of the work, a central office for receiving reports of sickness seems desirable. With a medical system as outlined, no objection could be raised to receiving reports over the telephone.

7. The reports of the surgeons should contain more facts of medical value, and should be more precise and complete from the scientific, descriptive and statistical point of view.

8. The surgeons should be relieved of the duty of testifying against malingering policemen at the trial court, whenever possible. This could be accomplished by requiring the men suspected of feigning prolonged sickness to appear before a board of three surgeons and by making the opinion of the board a basis for action by the Trial Commissioner.

9. The sanitary conditions of the dormitories of the Police precinct stations should be improved. Several suggestions with reference to the matter are contained in paragraph 7 of Part II of this report.

10. Several nurses should be attached to the office of the Chief Surgeon, to be used for investigations of home conditions of sick policemen and in connection with instructions in hygiene.

B. Of Remoter Application.—1. A change should be made in the Charter, allowing the discharge of men permanently incapacitated, even before the completion of ten years of service. Provisions should be made for a lump sum gratuity to the men so incapacitated, on the basis of the duration of service. The reasons for this recommendation are given in paragraph 3 of Part I of this report.

3. A change should be made in the Charter, providing for a surrender value of the moneys contributed toward the Pension Fund by the surgeons, on the basis of the duration of service.

The lack of such a provision may, under present conditions, act as a deterrent to the surgeons who enter the service at a comparatively early age and who, because of a large practice or other pressing obligation which might interfere with the proper discharge of Police Department duties, might wish to leave the Service.

C. Alternate Plan, Recommended in the Event that Treatment Is Given to Sick Members of the Force.—Should the suggestions made by the Committee as to the duties of the surgeons be impractical or against the policy of the Department, the Committee would suggest the organization of the larger work of the medical division on a basis different from what it is at the present time.

*This does not mean that the physical examinations should be spread over the entire year. It may be better to examine large numbers of policemen at certain specified times.

If the surgeons are to be requested to give adequate treatment to sick patrolmen and to do the other fundamental duties, the present staff of the medical division is inadequate. There will be need of additional medical service. The Committee would suggest that:

1. All the new appointees should give full time to the medical work of the Department, *i.e.* should not be permitted to engage in outside practice.

2. The new men should be appointed to the rank of medical inspector or assistant surgeon with a salary smaller than the present surgeons receive, but with the possibility of promotion with increase in salary.

The appointment system might, to advantage, be modelled after the Army Medical Service. It is the understanding of the Committee that in the organization of the medical division of the Fire Department some such system has been installed.

The maximum salary of the police surgeon doing full time work should be made higher than the present level of $3,500.

3. The clinic at Headquarters should be equipped adequately and enlarged, and a dental clinic should be added to it. The latter would do much toward preventing gastrointestinal and rheumatic disorders.

The Committee recommends also the employment of a chiropodist to attend to the minor foot ailments of the policemen.

The Committee suggests also the possibility of establishing such clinics in other boroughs, or what is still better, of making arrangements with the existing dispensary clinics for the utilization of their equipment at certain fixed hours, and that the patients be under the charge of surgeons of the Department.

4. Arrangements should be made with the City hospitals, and perhaps with certain private hospitals, for special rooms or wards for the more seriously sick or injured members of the police force. In such cases blank forms of record should be supplied to be filed and returned to the Department.

5. As it would be manifestly unfair to the surgeons now in the employ of the Department, who entered the service with a different understanding, to make them full time officers, the Committee would suggest that those who have appropriate specialties be put in charge of the clinic for a few hours every day in addition to certain other special duties to which they could be assigned.

6. The district work should be given to those of the surgeons who would consent to doing full time work, if their salaries were increased; and that newly appointed full time medical inspectors or assistant surgeons be put in charge of the districts.

7. It has been estimated that 1,000 persons is the maximum number of a group which a physician can undertake to care for under the health insurance plan. Applying this maximum to the Police force, it would become necessary to employ eleven full time district surgeons, if their duties are only those of treatment. As the duties of the surgeons include much more than treatment, and as the districts in New York are very large, it seems that there would be need of at least fifteen full time district surgeons, and probably ten additional surgeons to do special work in the clinics and to supervise the cases in hospitals.

8. As a system of medical care would require supervision of the cases treated at home, the Committee recommends that the Department employ a number of nurses to do visiting work. The nurses could be used also for making investigations of home conditions of patrolmen showing a high sickness rate, with a view of supplying the Medical Division with information which could be used in preventive work.

In presenting the foregoing impartial analysis and criticism, the Committee recognizes fully that the defects of the Medical Service exist partly through extraneous legislative action which at times has hampered progress. On the other hand, the Committee has been much impressed by the marked improvement in morale of the entire Police force, which has taken place under the present administration.

The Committee esteems it a privilege to have been invited to contribute suggestions for the betterment of the medical service. Should it seem desirable that any of the details which have been discussed in the report

be elaborated, the Committee would be happy at any time to co-operate further with the Commissioner.

Respectfully submitted,

THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.

March 5, 1917.

SUPPLEMENTARY RECOMMENDATIONS INVOLVING BUDGET APPROPRIATIONS FOR THE MEDICAL SERVICE OF THE POLICE DEPARTMENT.

Since it is the established policy of the Police Department to give medical treatment to sick members of the force, the matter of the best method of providing treatment for sick and disable patrolmen has been carefully reconsidered, and the following modified recommendations are made bearing on this particular phase of the report. It will be noted that these also will provide the necessary machinery for putting into effect the other recommendations of the original report, particularly that pertaining to the co-operation of City and private hospitals.

1. That the medical organization of the Police Department consist of (*a*) the chief surgeon; (*b*) the police surgeons; (*c*) the board of surgeons, composed of (*a*) and (*b*); and (*d*) the medical officers.

(*a*) The Chief Surgeon of the Police Department shall be a high grade full time officer, who shall be responsible for the activities and administration of the Medical Division of the Department. The office of Chief Surgeon shall be permanent and the incumbent shall be vested with well recognized and definite authority over all the employees of the medical service. His salary shall be $6,000 a year.

The requirements of efficient administration call for a responsible chief of the medical service, whose tenure of office would not be dependent upon political patronage and whose salary would be adequate to allow him to give up all outside professional interests.

(*b*) Under the suggested plan of having the treatment given by the medical officers, the Police Surgeons would act as administrative officers of the Department and their duties would consist in making examinations of men reporting sick and referring them to the proper medical officer for treatment, and in making examinations of applicants for admission to the Police force, for pensions and for reinstatements. They would also have to respond to emergency calls, attend Board meetings, and in rotation attend the clinic at Headquarters. The junior Medical Officers might relieve them of many of their duties when so ordered by the Chief Surgeon.

(*c*) The Board of Surgeons shall be continued. It shall remain as it has been in the past and its functions and duties shall remain unaltered.

(*d*) The treatment of sick policemen shall be carried on by a special medical corps known as Medical Officers of the Police Department. They shall be non-civil service, part time employees at $1,500 per annum. These Officers shall be recommended by the Chief Surgeon to the Commissioner for appointment. The Committee recommends that before confirming an appointment, the Commissioner shall ask the advice of some independent body of competent medical men not connected with the Police Department or the City administration. This recommendation is made in order that the Commissioner may not be dependent entirely upon the judgment of the Chief Surgeon, but may have the aid of a qualified body of experts of non-partisan composition.

The Medical Officers shall be graduates of a recognized medical school of first grade and shall have had at least one year of training in a general hospital. They shall not be eligible for appointment and shall not continue in this service after they have been out of the hospital as internes for more than five years. Their duties shall be assigned to them by the Chief Surgeons and shall consist in treatment of sick and disabled members of the Police Force whether at the homes of the patient, in the offices of the Medical Officers or in the clinic of the Police Department, and in visiting and reporting to the Chief Surgeon upon the condition of policemen under treatment in the various hospitals.

The Committee feels that complete and competent medical service can be obtained for the treatment of sick and disabled policemen by thus employing recent graduates of medical schools of high standards and paying them a reasonable compensation, such as $1,500 a year. By not making rigid requirements as to the consecutive number of hours these medical officers should be on duty, this position can be made attractive to a very high grade of medical men who, under competent administration, can render the City a large amount of service. In order to forestall any possibility of these medical officers falling into perfunctory routine work, the Committee recommends that their term of appointment should be no longer than five years and that they should be exempt from Civil Service.

The Committee feels that the training received by these Medical Officers would eminently qualify them for the position of Police Surgeon should they wish subsequently to secure appointments as permanent officers of the Police Department Medical Service.

On the basis of the figures of the average prevalence of sickness in the force and on the basis of what would constitute adequate medical attention, it was estimated that ten medical officers should be appointed at the present time and the number increased as need arises. If this addition to the medical staff be made, the present number of Police Surgeons will be found to be in excess of what will be needed, because as stated above, they will be relieved of the duty of treating patients. In view of this, it is the opinion of the Committee that no new Police Surgeons be appointed, and that vacancies occurring either by resignation or death be not filled until the number be reduced to twelve, or less, if twelve should prove more than are needed, each vacancy being met by the appointment of one additional medical officer.

The Committee desires to point out, however, that owing to the exigencies of the war, it will be impossible to obtain the services of men qualified to fill the new positions of Medical Officers at the present time, because practically all such men will be in the military service. The new organization, therefore, must await the termination of the war before being put into effect.

The Committee fully recognizes the fact that this plan will temporarily throw an additional burden upon the present Police Surgeons instead of granting the relief to which the increased force entitles them. However, the Committee feels no hesitancy in presenting the recommendations because it feels certain that the Police Surgeons will accept this burden as a part of their contribution to the military situation.

2. It is recommended that a staff of nurses be appointed to facilitate the work of the Medical Staff of the Police Department. Four should receive immediate appointment to organize the work, one of whom shall be assigned to duty at the Headquarters clinic and three of whom shall be assigned to duty on special cases and to such duties of investigation and home instruction as the Board Surgeons may designate.

3. The Headquarters clinic shall be fully equipped for the treatment of all types of ambulatory cases. It shall be open daily from 9 A.M. until 5 P.M. As need arises, other branch clinics shall be established.

Respectfully submitted,

THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.

June 18, 1917.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

TEXAS STATE BOARD OF MEDICAL EXAMINERS.

Austin, June 19, 20, 21, 1917.

ANATOMY.

1. Name the nerve tracts in the white substance of the spinal cord.
2. What vein and nerve are in the same sheath as the common caretid artery?
3. What structures would be severed in an amputation of the lower third of the thigh?
4. Name and give function of the cranial nerves.
5. Give origin, insertion, function, and nerve supply of the trapezius muscle.
6. Name bones of carpus and tarsus.

7. Describe the knee joint.
8. Give origin, course, and branches of the brachial artery.
9. What organs are supplied by the pneumogastric nerve?
10. Describe the sacroiliac articulation.

PHYSIOLOGY.

1. Define a cell and name its physiological properties.
2. State where fecundation of the human ovum may occur and explain the physiology of menstruation.
3. Describe the nervous mechanism of the heart.
4. Discuss the physiology of the pancreas.
5. Enumerate the functions of the lymphatic system.
6. Differentiate between: tidal, complemental, reserve, and residual air, and state the average respiratory capacity of an adult.
7. Discuss the physiology of the skin and name in the order of their importance the avenues through which the body heat is lost.
8. Define "internal secretion" and name the organs which produce such a secretion.
9. State the function of each of the anatomical divisions of the auditory organs.
10. A man is struck on the head and, without injury to the eyes, vision is lost. State the probable location of the lesion.

CHEMISTRY.

1. What test do you consider the most reliable for traces of arsenic? Briefly describe it.
2. Give common name for acetate of lead. How is chronic lead poisoning acquired? Antidote.
3. When corneal ulcer is treated with nitrate of silver what color does it give? Explain reactions.
4. Describe chlorine gas; how is it prepared and of what use is it?
5. Define double decomposition; valence; isomerism.
6. What is the difference between putrefactive and fermentative changes? Give examples.
7. Describe Trommer's test for sugar in urine. What is the reaction of normal urine? Specific gravity of normal urine?
8. Write an equation in which $HgSO_4$ will be found in the reaction.
9. Liberate bromine gas from bromide of potassium, and state the physical properties of the gas.
10. Give test and chemical antidote for morphine sulphate.

HYGIENE.

1. What hygienic measures should be taken to prevent malarial infection?
2. Give dietetic and hygienic management of scarlet fever.
3. Name some of the diseases contracted from drinking impure water.
4. Give hygienic care of pulmonary tuberculosis (latent).
5. What is pasteurization of milk? What are its advantages and disadvantages?
6. What diseases of the (*a*) spine, (*b*) skin, (*c*) respiratory tract, (*d*) digestive system are especially common in school children?
7. Give hygienic care of typhoid fever.
8. Name two good disinfectants and describe their application.
9. Differentiate: (*a*) endemic, (*b*) epidemic, and (*c*) pandemic diseases.
10. What hygienic considerations would influence you in the locating of a camp or mobilization site for an army?

ANSWERS.

ANATOMY.

1. *Nerve tracts in the white substance of the spinal cord:* Direct pyramidal tract, and the anterior fundamental column, in the anterior column; direct cerebellar tract, crossed pyramidal tract, lateral fundamental column, and anterolateral ascending tract, in the lateral column; column of Goll, column of Burdach, and Lissauer's tract, in the posterior column.

2. The internal jugular vein and the pneumogastric nerve are in the same sheath as the common carotid artery.

3. In amputation through the lower third of the thigh, the following structures would be severed: Skin; fascia; quadriceps extensor cruris, sartorius, adductor longus, adductor magnus, gracilis, biceps, semitendinosus, and semimembranosus muscles; femoral vessels, profunda and perforating branches, branches of external circumflex, comes nervi ischiadici, and internal saphenous vein; great sciatic, obturator, femoral, small sciatic, and external cutaneous nerves; the femur.

4. The special *names* by which the twelve pairs of nerves are generally known are: (1) Olfactory; (2) Optic; (3) Motor oculi; (4) Trochlear or Pathetic; (5) Trifacial; (6) Abducens; (7) Facial; (8) Auditory; (9) Glossopharyngeal; (10) Pneumogastric or Vagus; (11) Spinal Accessory; (12) Hypoglossal.

Functions: (1) Special sense of smell; (2) Special sense of sight; (3) Motor; (4) Motor; (5) General sensation and motor; (6) Motor; (7) Motor; (8) Special sense of hearing; (9) General sensation and special sense of taste; (10) Motor and general sensation; (11) Motor; (12) Motor.

5. TRAPEZIUS. *Origin:* external occipital protuberance, inner third of superior curved line of occipital bone, ligamentum nuchæ, spinous processes of seventh cervical and all the dorsal vertebræ. *Insertion:* outer third of posterior border of clavicle, acromion process, and spine of scapula. *Function:* draws back the scapula and shoulder, elevates shoulder, draws head to corresponding side, or if both act the head is drawn backward. *Nerve supply:* spinal accessory, and branches from third and fourth cervical nerves.

6. *Bones of carpus:* scaphoid, semilunar, cuneiform, pisiform, trapezium, trapezoid, os magnum, and unciform.

Bones of tarsus: os calcis, astragalus, cuboid, scaphoid, and internal, middle, and external cuneiform.

7. The *knee joint* is a ginglymus, and is formed by the condyles of the femur, the head of the tibia, and the patella. "The *external ligaments:* The *anterior* or *ligamentum patellæ* is the continuation of the tendon of the quadriceps extensor. Above it occupies the apex and rough marking on the lower and posterior surface of the patella; below it is attached to the lower part of the tubercle of the tibia. There is a bursa between the upper part of the tubercle and the ligament. The *posterior ligament* (*ligamentum posticum Winslowii*), broad and thin, covers the back of the joint. It consists of a central and two lateral parts. The lateral parts spring above from the femur above the condyles and are attached below to the head of the tibia. The central part is derived from an expansion of the semimembranosus tendon, and passes from the inner tuberosity of the tibia to the inner side of the upper part of the outer condyle of the femur. The *internal lateral ligament*, broad and flat, is attached above to the inner condyle of the femur; below, to the margin of the inner tuberosity, to the internal fibrocartilage, and to the inner surface of the shaft of the tibia for 1½ inches. The *long external lateral ligament*, a rounded cord, is attached above to the external condyle of the femur, and below to the external part of the head of the fibula, dividing the biceps tendon into two parts, a bursa intervening. The *short external lateral ligament*, very indistinct, lies parallel and behind the preceding, attached above to the outer condyle of the femur, and below to the styloid process of the fibula. The *capsular ligament*, thin, fills up the intervals between the special ligaments; it is attached to the margins of the articular surfaces of the bones, and blends with the fascia lata of the thigh; above it receives expansions from the vasti (*lateral patellar* ligaments).

"The *Internal Ligaments:* The *anterior* or *external crucial ligament* is attached to the depression in front of the spine of the tibia and to the external semilunar fibrocartilage; it passes upwards, backwards, and outwards to the posterior part of the inner side of the external condyle of the femur. The *posterior* or *internal crucial ligament* is attached to a depression behind the spine of the tibia, to the popliteal notch, and the posterior border of external semilunar fibrocartilage, this latter slip being sometimes called the *ligament of Wrisberg;* it passes upwards, forwards, and inwards, the posterior fibers attached by side of oblique curve of inner condyle, the anterior ones to the fore part of intercondylar fossa and to the anterior part of the outer

surface of the inner condyle. The *semilunar cartilages* are thicker at the circumferences than at the central margins, and serve to deepen the cavities for the head of the femur. The *internal semilunar cartilage* is oval in shape, the anteroposterior diameter being the longer. Its anterior extremity is attached to the tibia in front of the anterior crucial ligament, and the posterior extremity in front of the posterior crucial ligament. The *external semilunar cartilage* is nearly circular; its anterior extremity is attached to the tibia in front of the spine, the posterior extremity to the back of the spine." (*Aids to Anatomy.*)

8. The *brachial artery* is the direct continuation of the axillary, and extends from the lower border of the teres major muscle to about half an inch below the bend of the elbow, where it divides into the radial and ulnar arteries. The course of the artery is along the inner border of the coracobrachialis and the biceps muscles; at first it lies to the inner side of the humerus, but gradually passes to the front of that bone. It is superficial throughout its entire course. Its branches are the superior profunda, inferior profunda, anastomotica magna, nutrient and muscular.

9. *Organs supplied by the pneumogastric nerve:* Dura mater of brain, skin of external ear, pharynx, esophagus, stomach, larynx, heart, lungs.

10. The *sacro-iliac articulation* is an amphiarthrosis, formed between the lateral surfaces of the sacrum and ilium. The auricular or anterior parts of the articular surfaces are covered with cartilage, and connected by the two following ligaments:

The *anterior sacro-iliac ligament:* small bands passing obliquely from sacrum to ilium on the anterior surface.

The *posterior sacro-iliac ligament* consists of strong interosseous bands passing chiefly downwards and inwards from the rough part of the ilium behind the cartilage, to the posterior part of the sacrum. There are two *superior*, passing from the first and second transverse sacral tubercles, and one sometimes called the *oblique sacro-iliac* ligament, which reaches from the posterior superior iliac spine to the third transverse sacral tubercle. (*Aids to Anatomy.*)

PHYSIOLOGY.

1. *A typical cell* is the ultimate element of structure; it enters into the formation of all tissues. It consists of a tiny mass of protoplasm, and contains a nucleus and an attraction sphere, but as a rule no cell wall. Cells vary in shape and size (from about 1-3000 to 1-300 of an inch in diameter). The manifestations of cell life are: (1) Irritability, or power of responding to a stimulus; (2) power of movement; (3) power of assimilation; (4) power of growth; (5) power of excretion, and (6) power of reproduction.

2. It is believed that fecundation of the human ovum normally occurs in the outer end of the Fallopian tube.

Menstruation is a periodic discharge of blood from the mucous membrane of the uterus, due to a fatty degeneration of the small blood-vessels. Under the pressure of an increased amount of blood in the reproductive organs, attending the process of ovulation, the blood-vessels rupture, and a hemorrhage takes place into the uterine cavity; thence it passes into the vagina. Menstruation lasts from five to six days, and the average amount of blood is about five ounces. It begins at puberty and occurs periodically at about 28 days intervals, until the menopause; it is absent during pregnancy and early lactation.

The relation existing between ovulation and menstruation is not known. The two processes are usually coexistent, but they may be independent of each other. The following theories have been held: (1) Menstruation is dependent upon ovulation; (2) ovulation is dependent upon menstruation; (3) they are independent of each other; (4) they both depend upon some other (at present unknown) cause.

Menstruation has been considered as being analogous to the condition of "heat" or "rut" in the lower animals.

3. The nervous mechanism consists of an inhibitory and an accelerator supply. In addition, there are various intrinsic ganglia in the heart which are supposed to be responsible for the heart-beat. The *cardio-inhibitory* center is connected with the nucleus of the vagus in the floor of the fourth ventricle, and the fibers from it pass to the heart along the vagus nerve. Its function is to slow the beat of the heart. It is sometimes known as the anabolic center, because it lessens the rate and force of the heart and so allows time for building-up processes (anabolism). If the peripheral end of the cut vagus is stimulated, the heart is slowed and may be entirely stopped. It is a tonically active center, that is, it acts continuously, so that the simple cutting of the vagus takes off the brake and lets the heart run away.

The *cardio-accelerator* center is also in the floor of the fourth ventricle. It acts through the sympathetic fibers which descend in the spinal cord and leave it through the anterior roots of the first and second dorsal nerves, and go thence to the cardiac plexus. This center keeps up the rate of the heart beat.

These centers may be stimulated by afferent impulses, such as *psychic* from the cortex cerebri, or *cutaneous*, or *visceral*. The centers are also affected by the state of the blood; thus excess of carbon dioxide in the blood, as in the beginning of asphyxia, stimulates the cardiac centers and makes the heart beat more strongly and more rapidly. Increased temperature of the blood also increases the rapidity of the heart's action.

4. The *functions of the pancreas* are: (*a*) The secretion of the pancreatic juice, which (1) changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin; (2) converts starch into maltose; (3) emulsifies and saponifies fats, and (4) causes milk to curdle. (*b*) The manufacture of an internal secretion.

5. The *function of the lymphatic system* is to provide the tissues with material necessary to their functional activity, growth, and repair; to receive from the tissues their waste products; and to convey the products of digestion and absorption to the blood-current.

6. *Tidal air* is the air which is constantly passing in and out of the lungs during ordinary calm respiration. It measures about 30 cubic inches.

Complemental air is the air which can be taken in beyond what is normally inspired in ordinary breathing. It measures about 100 cubic inches.

Reserve air is the air which can be expelled at an extraordinary expiration. It measures about 100 cubic inches.

Residual air is the air which still remains in the lungs after the deepest expirations. It measures about 100 cubic inches.

Respiratory or *vital capacity* is the amount of air which can be expelled from the lungs by an extraordinary expiration after the most forcible inspiration. It includes the tidal, complemental, and reserve air, and measures about 225 to 230 cubic inches.

7. The *functions of the skin* are: (1) Protection, (2) excretion, (3) secretion, (4) heat regulation, (5) absorption, (6) general sensation, (7) special sense of touch, and (8) respiration.

(1) By its mechanical covering, and also by its being an organ of sensation. (2) Very slight; and see (3). (3) It secretes sebum to lubricate the hairs, and sweat (which has several functions: excretion of water, carbon dioxide, and urea; cooling of surface of body; and regulator of body heat). (4) By radiation, and see 3. (5) Very slight, chiefly of oily substances. (6) and (7) By end organs. (8) A slight amount of carbon dioxide is exhaled.

Body heat is lost mainly through the skin, the lungs are next in importance, and a very small amount is lost in the urine and feces.

8. *Internal secretions:* It is generally held now that the glandular organs, chiefly the pancreas, liver, and the ductless glands, produce a secretion, peculiar in each case to the particular gland producing it, and which is supposed to be given off to the blood or lymph, and to have some peculiar value in the general metabolism of the body. Such secretions are called internal secretions, in contradistinction to the previously known secretions, which are carried off by a duct, and are known as external secretions. Very little is definitely known of these internal secretions, but much work is being done on the subject.

Internal secretions are produced by the liver, pancreas, ovaries, testes, thyroids, parathyroids, spleen, suprarenals, pituitary body, and by the fetus.

9. "The function of the *auricle* is to collect the sound waves and direct them to the *membrana tympani*. The concha is especially important for this purpose, as well as the cavity just beneath the tragus. After the sound waves have reached the *drumhead* through the *external auditory canal*, they are transmitted by the *chain of ossicles* to the fluid of the labyrinth, the ossicles probably vibrating as whole bodies. The sound waves then pass through the fluid in the *cochlea* and reach the *organ of Corti*. From the nerve filaments in the cochlea the sensations called sound are conveyed through the *auditory nerve* to the brain center."—(Bacon's *Manual of Otology.*)

10. The lesion is probably in the occipital lobes.

CHEMISTRY.

1. For the practitioner of medicine the most reliable test for arsenic is *Reinsch's test*, as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

2. The common name for acetate of lead is sugar of lead.

Sources of chronic lead poisoning: Contamination of drinking water which has been in contact with lead; the use of food or chewing tobacco which has been wrapped in tinfoil containing excess of lead; drinking of beer or other beverages which have been in contact with pewter; handling of lead or its alloys, manufacturing processes in which lead or its compounds are used. Antidote for lead is magnesium sulphate.

3. If a corneal ulcer is treated with nitrate of silver, a black discoloration results. This is due to the decomposition of the silver nitrate when it comes in contact with an organic substance; this decomposition results in the separation of the silver, and the deposit of this silver causes a black stain.

4. *Chlorine gas* is a greenish yellow gas, with a penetrating odor, and very irritating to the respiratory passages; it is soluble in water, is more than twice as heavy as air, it combines readily with many elements, and is readily fixed by many organic substances, either by addition or by substitution. In the presence of water, chlorine is an active bleaching and disinfecting agent.

It may be *prepared* by heating together manganese dioxide and hydrochloric acid:

$$MnO_2 + 4HCl = MnCl_2 + 2H_2O + Cl_2.$$

It is *used* as a bleaching and disinfecting agent, and also in the preparation of such agents.

5. A *double decomposition* occurs when two substances mutually react upon each other with the formation of new substances, as:

$$2KHO + H_2SO_4 = K_2SO_4 + 2H_2O.$$

Valence is the combining power of an atom of an element as compared with that of an atom of hydrogen.

Isomerism: Two substances are said to be isomeric when they have the same percentage composition.

6. *Putrefactive changes* only occur in proteid matter.

Fermentative changes only occur in non-nitrogenous organic matter.

7. *Trommer's test for sugar in urine:* To the suspected urine, in a test-tube, add about one-eighth of a 1:10 solution of sodium hydroxide or potassium hydroxide; then add two or three drops of a 1:10 solution of copper sulphate; shake and boil. If sugar is present, a yellow or red precipitate of cuprous oxide is formed.

The *reaction* of normal urine is acid.

The *specific gravity* of normal urine is about 1015 to 1025.

8. $HgSO_4 + 2NaCl = Na_2SO_4 + HgCl_2$.

9. *Bromine* may be liberated from bromide of potassium by heating with strong sulphuric acid and manganese dioxide:

$$2KBr + 3H_2SO_4 + MnO_2 = 2KHSO_4 + MnSO_4 + 2H_2O + Br_2.$$

Bromine is a very heavy, mobile, dark-red liquid, with a very offensive odor, and an irritating action on the mucous membranes; when boiled the vapor has the same color as the liquid; it is soluble in a number of liquids.

10. *Test for morphine:* Solution of neutral ferric chloride gives a blue color with morphine.

There is no recognized *antidote* to morphine. Atropine will overcome the respiratory depression; black coffee or strychnine will act as a stimulant; a weak solution of potassium permanganate is very serviceable.

HYGIENE.

1. *Prophylaxis of malaria:* Individuals should use mosquito netting around their beds and wire gauze in doors and windows so as to keep out the mosquitoes as much as possible. During residence in malarial districts quinine should be taken every morning before breakfast. All pools, stagnant water, etc., where *anopheles* may breed, should be removed. All mosquitoes, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darkness, opportunities for infection may be avoided. Occasional fumigation with formaldehyde or sulphur is also beneficial.

2. *Dietetic and hygienic management of scarlet fever:* "A quiet sunny room that can best be used for purposes of isolation should be selected. An open fireplace is preferable to any other form of heating. All unnecessary furniture should be removed, a gown or sheet and a bowl of bichloride of mercury 1-1000 shou'd be placed in readiness in an empty closet outside of the room for the use of the doctor. During convalescence toys of little value, that can be burned, should be provided, so that the period of quarantine, which is usually six weeks, may not be too irksome for the child. Disinfection can be carried out when the patient is ready to be discharged. All cases of scarlet fever, whether mild or severe, should be regarded as dangerous, as the complications and sequelæ may permanently injure the patient. Skilled nursing will do more to promote the comfort, progress, and the prevention of complications than remedial measures. If circumstances will not permit of a trained nurse, some one member of the household should be put in charge and given careful instructions as to the quarantine regulations and written orders for the patient. *The diet* should consist wholly of milk in the first few days of the illness; later, for the sake of variety, fruit juices, whey, buttermilk, or matzoon may be added or substituted. When convalescence is established, gruels, crackers, well-toasted bread, and apple sauce may be added to the dietary. Vegetables and eggs are allowed in the fourth or fifth week if there is no fever or other contraindication. Water shou'd be offered often and freely throughout the illness." (Chapin and Pisek's *Diseases of Children.*)

3. *Diseases carried by infected water:* Typhoid, cholera, dysentery, diarrhea, indigestion, goiter, intestinal worms, and lead poisoning.

4. *Hygienic precautions to be taken in case of tuberculosis:* "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*)

5. *Pasteurization of milk* consists in heating the milk for twenty minutes at a temperature of 140° F.

"Advantages of the pasteurization of milk: (1) That most, if not all, of the common bacteria and their toxins are killed. (2) That the ordinary ferments and germicidal properties of the milk are not destroyed. (3)

That the process may be accomplished on a large scale, and furnish a commercially safe milk. (4) That the taste, appearance, odor, and cream separation quality of the milk are not altered. (5) That pasteurized milk, if kept cold, furnishes a clean, healthy milk, safe for infant food and other uses.

"Disadvantages of the pasteurization of milk: The following are some of the objections which are urged by the opponents of pasteurization upon a large and commercial basis: (1) That the spore-bearing bacteria and bacterial toxins are not destroyed, and the milk is therefore not wholly safe. (2) That pasteurization stops lactic-acid fermentation, and thus destroys the only 'nature's danger signal,' and the first symptoms by which aged milk is known. (3) That unless pasteurized milk is rapidly cooled and kept under 50° F., certain fermentative changes which are ordinarily stopped by lactic-acid fermentation increase in activity, owing to the destruction of lactic-acid bacilli by the pasteurization. (4) That pasteurization, by preserving unclean milk for some time, may induce the producers to furnish dirty milk, discourage rigid cleanliness, and promote carelessness on the part of the producer who relies entirely on the pasteurization to preserve the milk. (5) That the pasteurization furnishes a 'purified' milk instead of a 'pure milk.'"—(Price's *Hygiene and Sanitation.*)

6. *Diseases prevalent in school children. Skin:* Pediculosis, scabies, ringworm, as favus, impetigo. *Respiratory:* Bronchitis and bronchopneumonia. *Spine:* Scoliosis, kyphosis, and lordosis. *Digestive:* Constipation, gastritis, anorexia, diarrhea.

7. In *typhoid fever* the patient should be placed in bed in a quiet and well-ventilated room; an intelligent nurse is necessary. The utmost cleanliness of the patient, bedding, sick-room requisites, etc., must be observed. The patient's strength must be conserved in every way possible; the infection must not be allowed to reach others; the diet must be suited to the patient, and must be given frequently; drugs are only to be given when there is a distinct need for them; the patient must be carefully watched for the first sign of complications; the best method for reducing the body temperature is generally held to be the use of the Brand bath; the patient should be allowed plenty of water to drink.

To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; all the milk should be boiled also, if any cases of typhoid fever are in the neighborhood; and no ice should be put in water or other drink or food.

8. *Two good disinfectants:* Sulphur dioxide, and formaldehyde.

"Sulphur dioxide, SO_2, though not so positive in its action as chlorine, is much more frequently employed on account of the lesser risk and trouble connected with it. It probably kills the germs not containing spores if sufficiently concentrated and in the presence of moisture, and is, therefore, useful in the fumigation of rooms and of articles that cannot be subjected to steam heat or chemical solutions. But it will bleach or tarnish many articles, and for this reason and the fact that it is much inferior to formaldehyde, it will hereafter probably be almost entirely supplanted by the latter whenever that can be obtained. To secure sufficient concentration at least three pounds of sulphur should be burned for every 1000 cubic feet of air-space, care, of course, being taken that there may be no risk of igniting the floor or any articles in the room."—(Egbert's *Hygiene.*)

"Formoldehyde gas has greatly superseded sulphur dioxide as a disinfectant. Its main value is that, while it is a good germicide, it does not destroy fabrics and injure objects as the latter, and also it is nontoxic. Formaldehyde is also but a surface disinfectant, its penetrating qualities not being very great. Bacteria are killed by formaldehyde immediately on direct exposure, and spores within an hour. It kills dried organisms as well as those in a moist state. Formaldehyde is not an insecticide. For domestic disinfection formaldehyde is generated by spraying liquid formalin (which contains 40 per cent. of the gas), or by heating paraform pastils or powder, also by means of generators or lamps. Other methods of evolving formaldehyde in disinfection which are used in large house and hospital disinfections are by means of large generators or lamps, or in specially constructed autoclaves under pressure, or in retorts without pressure."—(Price's *Hygiene and Public Health.*)

9. An *endemic disease* is one which is peculiar to a district or is limited to a class of persons.

An *epidemic disease* is one which affects at the same time a large number of persons in a community; or one which spreads rapidly, and attacks many persons.

A *pandemic disease* is one which affects at the same time large numbers of persons in many countries.

10. *In selecting a camp site* the following conditions should be borne in mind: The presence of water, wood, and grass. The soil should be dry and elevated, with enough protection from winds. There should be space enough to accommodate the men without crowding. Old camp sites should be avoided because the soil is certain to be polluted and may be infected. Excess of vegetation and dense woods should be avoided on account of the extreme moisture or dampness which they induce. Marshes and stagnant water should also be avoided on account of mosquitos.

(To be continued.)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	W. H. Sanders, Montgomery	Montgomery
Arizona*	J. W. Thomas, Phoenix	Phoenix Oct. 2
Arkansas	T. J. Stout, Brinkley	Little Rock Nov. 13
California	C. B. Pinkham, Sacramento	Los Angeles Oct. 9
Colorado	David A. Strickler, Empire Building, Denver	Denver Oct. 2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven Nov. 13
Delaware	J. H. Wilson, Dover	Dover Dec.
Dist. of Col'bia	E. P. Copeland, Washington	Washington Oct. 9
Florida*	W. M. Rowlett, Tampa	Jacksonville Dec. 4
Georgia	C. T. Nolan, Marietta	Atlanta Oct. 9
Idaho*	Charles A. Dettman, Burke	Pocatello Oct. 2
Illinois	F. C. Dodds, Springfield	Chicago Oct. 9
Indiana	W. T. Gott, Crawfordsville	Indianapolis Jan. 8
Iowa	G. H. Sumner, Des Moines	Des Moines Oct. 9
Kansas	H. A. Dykes, Lebanon	Topeka Oct. 9
Kentucky	J. N. McCormack, Bowling Green	Louisville
Louisiana	E. L. Leckert, New Orleans	New Orleans Dec. 6
Maine	F. W. Searle, Portland	Portland Nov. 13
Maryland	J. McP. Scott, Hagerstown	Baltimore Dec. 11
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston Nov. 13
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing Oct. 9
Minnesota	T. McDavitt, St. Paul	Minneapolis Oct. 2
Mississippi	J. D. Gillevlen, Jackson	Jackson
Missouri	G. H. Jones, Jefferson City	Kansas City
Montana*	Wm. C. Riddell, Helena	Helena Oct. 2
Nebraska	J. J. Homres, Lincoln	Lincoln Nov. 14
Nevada	S. L. Lee, Carson City	Carson City Nov. 5
N. Hampshire	Walter T. Crosby, Manchester	Concord Dec. 10
New Jersey	A. MacAlister, Trenton	Trenton Oct. 16
New Mexico	R. K. McClanahan, Santa Fe	Santa Fe Oct. 8
New York	H. H. Horner, Univ. of State of New York, Albany	New York Albany Oct. 2 Syracuse Buffalo
N. Carolina	H. A. Royster, Raleigh	Raleigh June
N. Dakota	G. M. Williamson, Grand Forks	Grand Forks Jan. 1
Ohio	, Columbus	Columbus Dec. 4
Oklahoma	R. V. Smith, Tulsa	Oklahoma City Oct. 9
Oregon	B. E. Miller, Portland	Portland Jan. 7
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia Jan.
Rhode Island	R. V. Richards, Pawtucket	Providence Oct. 4
S. Carolina	H. E. Boozer, Columbia	Columbia
S. Dakota	P. B. Jenkins, Waubay	Pierre Jan. 8
Tennessee	A. B. DeLoach, Memphis	Memphis Nashville June Knoxville
Texas	M. F. Bettencourt, Mart	Austin
Utah	G. F. Harding, Salt Lake City	Salt Lake City Oct. 1
Vermont	W. Scott Nash, Underhill	Burlington Feb. 12
Virginia	I. W. Preston, Roanoke	Richmond Dec. 11
Washington*	C. N. Suttner, Walla Walla	Spokane Jan. 1
W. Virginia	S. L. Jenson, Charleston	Clarksburg Nov. 21
Wisconsin	J. M. Dodd, Ashland	Madison Jan. 14
Wyoming	H. E. McCollum, Laramie	Laramie Oct. 10

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Books Received.

Miscellany.

The Spanish Medical Congress of 1918.—The great European War will not be allowed to interfere with the activities of next year's Spanish National Medical Congress, apparently the first of its kind. The session will be held in Madrid on April 21-26, under the presidency of Ramón y Cajal and others. The number of sections will be seventeen. Of the topics for symposium treatment the majority present nothing of especial novelty.

Under the section of "medical literature, bibliography, etc.," we note two movements of interest. One is directed toward the establishment of a Spanish Index Medicus and the other refers to the "Castellanization," or Spanishing, of technical terms. This may refer to a uniform orthography and pronunciation of foreign technical terms or it may go much deeper and seek to substitute modern Spanish words for exotic expressions.

Another national movement apparently refers to listing all the medicinal mineral springs in respect to properties and uses, central control, etc. One theme for discussion is "spectrum analysis of spring waters." Papers on various aspects of tuberculosis which occur under a number of sections show the great importance of the subject. Echoes of the war are seen chiefly in such papers as "hygiene of the submarine," "reeducation of the mutilated," "neurology of the war," and "odontology of the war."

One of the sections, No. VII, is quite novel; it covers "pedopathy, puericulture, mothercraft, and eugenics" and is under the direction of Vargas of Barcelona. Despite its portentous title, the subjects for general discussion are limited to "infantile colitis" and "infantile tuberculosis." The double section of anatomy and physiology, Chairman Dr. P. Suner, has as a general theme "physiological factors of diuresis." There is a subsection under Internal Medicine on "nutrition, hematology, and endocrinology," the open papers to be devoted to "opotherapy" and "lymphadenias." The remainder of the program contains nothing of unusual interest.

The Death Rate in Rio de Janeiro.—This seems to have been unusually high last June, a winter month. During the week of June 10-16 inclusive there were 422 deaths, a daily average of 60, as against 50 in the same week of 1916. In the week of June 3-9 inclusive the daily average was 65. A third of the deaths were due to transmissible diseases, tuberculosis leading with 93 for the week. There were no epidemics, but deaths from acute contagious diseases amounted to more than 50. There were 74 deaths of infants under one year of age. Deaths from diseases of the circulatory and digestive apparatuses numbered 62 and 63 respectively. Malignant tumors claimed but 12 victims. Since the births (604) far exceed the deaths, it is probable that the increased numbers are due to the natural growth of the city, although no figures are forthcoming. There was but a single death from diphtheria, which is about the usual weekly toll, a document to the infrequency and mildness of this affection in Rio.

A CRITICAL ANALYSIS OF THE TREATMENT OF TUBERCULOSIS WITH COPPER AND POTASSIUM CYANIDE.*

BY GEORGE H. EVANS, M.D.,

SAN FRANCISCO, CAL.

ASSISTANT PROFESSOR OF CLINICAL MEDICINE, UNIVERSITY OF CALIFORNIA MEDICAL SCHOOL.

THE brilliant achievements of Ehrlich in the chemotherapy of syphilis have anew called the attention of the medical profession to the possibility of the discovery of a specific for tuberculosis among the metallic substances used in medicine. Attention for the meantime has been to a certain extent diverted from biologic remedies by the impetus given by the researches of Meissen, von Linden, Dewitt, Koga, and others in the field of chemotherapy. In these studies, gold, copper, arsenic, iodine, and other substances have had their respective advocates, and results of animal experimentation and clinical experience have been presented, sometimes with an enthusiasm which would almost suggest that the great panacea for tuberculosis was in our hands. A critical analysis, however, usually demonstrates that the optimism of the therapist has been responsible for deductions not in accordance with the actual results, and thus remedy after remedy is brought forth only to be consigned to therapeutic oblivion.

A curious misapprehension popularly exists in the mind of the public, and to a certain extent in that of the profession, that a specific remedy for tuberculosis is possible in the sense that such specifics exist for malaria, diphtheria, or even syphilis. This is due to the popular misapprehension concerning the pathology underlying chronic phthisis in the adult, the result and development of tuberculosis which has existed since early childhood.

Thus we see these remedies presented and advocated as specifics, based on the result of animal experimentation. It is quite a different thing to inhibit or even heal a recent tuberculous lesion experimentally produced, from successfully attacking bacilli firmly intrenched behind impenetrable barriers of fibrous tissue, the result of years of development. We read much in literature concerning the curability of early tuberculosis. It is time we changed our views in accordance with the facts brought out by modern studies of phthisiogenesis, and recognized the fact that incipient pulmonary tuberculosis in the adult does not exist; that phthisis is a pathological process, the result of years of tuberculous disease, where, in the favorable cases, processes of destruction and repair have gone on hand in hand. The lessons of the autopsy table surely teach this.

Last year Koga, working in the Kitasato Institute for Infectious Diseases in Tokyo, presented two contributions to the chemotherapy of tuberculosis. After considerable experimentation with different substances and different solutions of the same substances, he prepared a double salt of copper and potassium cyanide, put up in dilution of two milligrams of the salt to the cubic centimeter of diluent. The results recorded by him were such as to justify a careful clinical trial of the merits of the preparation. Through the kindness of Dr. Koga a sufficient amount of the remedy for study was placed at my disposal, and the following case records are from my wards in the tuberculosis department of the San Francisco General Hospital.

The criticism will at once be made that an insufficient number of patients has been studied on which to base any conclusions as to the value of the remedy. Such criticism must be met by the statement that a critical analysis of a few cases intensively studied and carefully observed affords a better basis for subsequent study than does a large clinical material where the facilities are frequently not such as to allow of such intensive study and observation.

Out of a service of about seventy beds, ten patients were selected for treatment. The service in this department is for the reception of late cases only, and the preparation therefore was put to a rather severe test. On the other hand, the favorable results usually accomplished by dietetic-hygienic treatment on the earlier cases generally renders any conclusion impossible as to the value of this or that remedy which may have been tried.

The cases selected presented a variety of tuberculous lesions and complications and were chosen without much regard to their severity, in the attempt to determine better the immediate effect of the preparation upon tuberculous tissue generally.

In the examination of these patients, careful records and studies were made of the blood, urine, functional kidney tests, amount and content of sputum, etc., and other chronic conditions were ruled out as far as possible. With one exception the Wassermann blood-serum test was negative. Tubercle bacilli were present in the sputum of all

The preparation was used in doses varying from eight to twenty-one milligrams, and was invariably given intravenously, a vein in the elbow being chosen. Scarcely any difficulty was experienced in the administration. Occasionally some soreness and temporary induration were experienced by a

*Read at the eighteenth annual meeting of the American Therapeutic Society, held June 1 and 2, 1917.

few drops of the material getting into the perivascular tissues. The patients were confined to bed during the first week following each injection, some of them during the entire course of the treatment. Those who were allowed up were strictly limited as to their activity.

It was administered at intervals of two weeks following the plan of Dr. Koga.

Case I.—Walter P., age 29, a waiter, born in the United States, entered the San Francisco Hospital December 6, 1916, complaining of cough, weakness, loss of weight and pain in the left chest. He had a cough eighteen years ago, and was told then that he had tuberculosis. He apparently recovered and enlisted in the army. He had had several attacks of tonsilitis, and a fistula in ano was operated upon last May. His present illness had begun two years before with a severe cold. He lost weight, became weaker and had night sweats. His weight on entrance was 142 pounds, representing a loss of 46 pounds. He had used alcohol to excess, denied Neisser or luetic infection, had chancroid when in the Army.

Examination showed a man somewhat emaciated, with dullness over both upper lobes, rales in the right upper lobe, and signs of cavity in both apices. His urine was negative, with a total phenolphthalein output of 58 per cent. Blood examination was negative. Wassermann blood serum test negative. Tubercle bacilli were present in the sputum, Gaffky 1.

Treatment: On January 14, 1917, 8 mg. of the copper and potassium cyanide was administered intravenously; it was almost immediately followed by a chill of 10 minutes' duration. The following day showed a rather prompt rise in temperature and pulse, soreness in the chest, with slight increase in rales. There was some soreness around the scar of the old fistula in ano, which appeared inflamed. On January 28, two weeks later, 12 mg. were injected, followed by slight dizziness. The next day there was again soreness in the chest. The sputum, however, had decreased, the cough was less, and no bacilli were found. On February 12, 12 mg. No general reaction followed this, but the next day there was some increase in sputum and pain in the chest. There was some local pain in the arm for some time following this injection. February 26, 16 mg. were given, followed by considerable perivascular infiltration and some increase in the sputum, which was blood streaked. March 12, 17 mg. was given without reaction. March 29, 12 mg. was injected. The next day showed a slight increase in the number of bacilli, but no general reaction.

This man's weight increased from 136 pounds to 145 pounds during the treatment. While his general condition seemed considerably improved, there was very little change in the physical signs, and bacilli were still present.

Case II.—Chris. F., a student, 21 years of age, born in the Philippine Islands, entered the San Francisco Hospital November 16, 1916, complaining of cough, hoarseness, weakness, and night sweats. He had lived for the past four years in San Francisco. The only history of significance was an attack of smallpox when four years of age. He denied symptoms of his present illness before September, 1916, at which time he began to have a slight morning cough and pain in the chest; later hoarseness developed, which had increased; in October night sweats appeared. His weight on entrance was 109 pounds.

Examination showed a fairly well developed and nourished young man, well pock-marked, with bad tonsils and poor oral hygiene. The larynx showed ulcerations on the right cord. The chest was normal in shape, with considerable regional emaciation and extensive tuberculous involvement of both lungs, more marked on the left, and cavity formation in the left upper lobe. The heart was small. Blood pressure 138, 98. Urine negative, with a phenolphthalein output of 45 per cent. Blood and Wassermann negative. Tubercle bacilli in the sputum.

Treatment: On January 15, 1917, 8 mg. of the double salt was given, followed by a chill lasting 15 minutes. The next day there was focal reaction shown by slight increase in the sputum and some pain in the throat. On January 29, 15 mg. was given, followed the next day by a slight increase in sputum. On February 12, 8 mg. This was not followed by any reaction. February 26, 12 mg.; no reaction except some local induration at the site of the injection. He stated that his throat was considerably better. On March 4, six days after the last injection, he developed a sudden pain in the chest, with sharp rise of temperature to 104°. A spontaneous pneumothorax had occurred on the left side. This was accompanied by painful respiration, increased pulse, and slight increase in the sputum. The next day the sputum had markedly decreased. On March 13 fluid was present in the left pleura in considerable quantity. Thoracentesis (5 c.c. withdrawn) showed a clear transudate; 14 mg. of the cyanide salt was given, with no evidence of reaction. The temperature remained high. On March 26 the pleural fluid was decreasing in quantity. On April 26 his hoarseness continued, the pleural fluid had apparently been entirely absorbed, and the temperature had been nearly normal for three weeks. Sputum was present in negligible quantities. His weight, which was 105½ pounds at the beginning of treatment, decreased during the attack of pneumothorax, but increased again to 103¼ pounds.

There was very little change in the condition of the lungs except that produced by the changes in the pleura. There was no demonstrable fluid remaining. The larynx had not improved. This man was very optimistic and thought he was better, but the prognosis is bad. He still had bacilli in his sputum, Gaffky 2.

Case III.—Karl S., age 31, single, cook, born in the United States, entered the San Francisco Hospital on December 18, 1916, complaining of cough and shortness of breath, which had existed for seven months. He had had night sweats for six months, and a week before there had been blood in his sputum. He had been subject to frequent colds for the past twenty years. Admitted Neisser infection; denied lues. Had formerly used alcohol excessively. Lately his appetite and digestion had been disturbed and there had been considerable dyspnea. Temperature on entrance was 100°, pulse 85.

Examination showed both lungs involved in an extensive tuberculous process, with cavity formation at the left apex. The *x*-ray plate showed considerable mottling throughout the right lung, with dense fibrous shadow in the left upper lobe. The heart was ptosed. The bases were fairly clear, the left emphysematous. the diaphragmatic domes well marked. The sputum contained tubercle bacilli, Gaffky 3. Urine and blood were negative, except that the Wassermann in this instance was ++. (This was the only case in the series presenting a positive Wassermann.)

Treatment: January 16, 1917, 8 mg. of the double salt was given, followed by a slight chill and some headache. January 29, the man's general condition was much improved—rales had diminished and there was less cough; 16 mg. was administered, followed that night and the next day by pain in both sides of the chest, some increase in rales on both sides, and increase in sputum. Two days later there was a decided increase in his leucocytes. On February 12 there were very few rales present—decidedly decreased in number in both apices; 12 mg. administered. This was followed by slight pain at the site of injection. There was no focal or general reaction. Sputum had disappeared. On February 16 he felt well and wanted to leave the hospital, which he later did without permission.

This man's weight increased from 133 pounds to 142½ pounds. His sputum, which was quite abundant at the beginning of the treatment, steadily decreased, and after the increase marking the reaction from the second injection, entirely and permanently disappeared.

Case IV.—Gustav P., age 59, single, a Russian sailor, entered the San Francisco Hospital December 4, 1916, complaining of cough, much sputum, dyspnea, loss of weight, and recent hemoptosis. His father died of tuberculosis. Patient had at times been immoderate with alcohol; denied venery. His present trouble began about four years ago with a cough which had gradually increased. Occasional fever, night sweats, and chest pains on the left side. During past two years had lost 20 pounds in weight. For past year he had had nausea and vomiting, with weakness, cough, and dyspnea.

Examination showed a man fairly well developed, without marked emaciation. Fingers clubbed. He had an emphysematous chest with considerable muscle atrophy in the clavicular fossæ, with dullness over the upper lobes and hyperresonance below. He had excessive crepitation through both lungs, with marked asthmatic rales on both sides. There was cavity formation in the left upper lobe. Examination of the heart was negative. Blood pressure 105, 70. Urine was negative. Phenolphthalein function 53 per cent. Blood count and Wassermann negative. Sputum contained tubercle bacilli, Gaffky 3. Tuberculin reactions were mild and delayed, both cutaneous and intracutaneous. *X*-ray plate of his chest showed extensive mottling throughout both lungs, with much fibrosis in the apices.

Treatment: 12 mg. of the copper and potassium cyanide was given on January 18, 1917, followed by an increase in the number of rales, some chest pain and traces of blood in the sputum. No general reaction. On February 1, the second dose, 16 mg., was given. Following this there was some increase in the number of leucocytes, the sputum became thicker and a few blood clots appeared on the second day. February 15, 14 mg. The next day there was slight pain in the chest and the sputum had somewhat increased. There was also some local tenderness at the site of injection. March 1, 16 mg. was given, with evidence of focal reaction, the rales again being increased, with some increase in the bacillary content of the sputum. During this time, and since his entrance, he had been continuously vomiting in the morning, with considerable burning sensation in his stomach; this had been relieved by alkalis. March 15, 13 mg., without any evidence of reaction.

This man's weight increased from 137 lbs. to 145 lbs. His physical signs had improved somewhat, although the bacillary content remained about the same. There had been very little change in the actual amount of sputum compared with the beginning of treatment. Traces of blood were frequent during treatment, but with very little relation to the time of injection. The man was of the emphysematous, fibroid type, essentially chronic, where one frequently sees periods of remission regardless of any treatment. His mental attitude toward his disease was, of course, very much improved.

Case V.—Bernard O., Italian laborer, age 27, entered the San Francisco Hospital December 28, 1916, without a very satisfactory history. As far as it could be obtained, his disease had begun 3½ months before, with cough, sputum, night sweats and hemoptysis. He had dissipated considerably and his weight had decreased from 140 lbs. to 106 lbs. He had been steadily failing since his entrance to the hospital and had been running a high septic temperature with correspondingly rapid pulse.

Examination of the chest showed extensive bilateral disease with probable cavity formation in both apices. There was, in addition, considerable laryngeal ulceration and he was coughing large amounts of sputum, Gaffky 7.

The prognosis was considered hopeless in this case. He gained somewhat in weight during his stay in the hospital, and at the time treatment was commenced had increased to 119 lbs., but temperature and pulse were still running very high.

Treatment: Three injections of the double salt were given, of 6, 7 and 10 mg. respectively, at intervals of two weeks. Aside from a chill lasting 20 minutes following the first injection, no symptoms referable to the injection could be determined.

He lost steadily and died 40 days following the first injection. His temperature, pulse, sputum, and throat symptoms remained unchanged during this time. Autopsy showed extensive tuberculous involvement of both lungs, with large cavity formation. There was no evidence of tuberculosis in any of the other organs.

Case VI.—Henry B., a Swiss laborer, age 48, single, entered the San Francisco Hospital November 13, 1916, complaining of cough, weakness and loss of weight. He denied venery, had always been moderate in his habits, and had always been well and strong until six years before, when he sustained a compound fracture of the leg. During the following 16 months he had lost in strength and weight and suffered from malaise. Six months before entrance he had severe pleural pains in the left side of the chest, followed shortly by a brisk hemorrhage. Cough had persisted and steadily increased. He had a second hemorrhage one month after the first, and since has had occasional night sweats and intermittent attacks of fever. Recently coughing had produced vomiting. No intestinal disturbance.

Examination showed a poorly developed and nourished man, markedly emaciated. There was an extensive tuberculous process involving both lungs, more marked on the left, with cavity formation in the left upper lobe. The heart was displaced somewhat to the left, apparently the result of adhesions. His abdomen showed his liver somewhat enlarged and tender, the spleen was palpable, and there was considerable tympanites. Tuberculin reactions, cutaneous and intracutaneous, were delayed and mild. Blood pressure 115, 75. Urine, chemical, microscopical and functional, negative. Blood and Wassermann negative. Sputum contained tubercle bacilli, Gaffky 3.

Treatment: January 23, 1917, copper and potassium cyanide, 12 mg., followed the next day by headache and some increase in rales. February 6, the sputum had very much decreased in quantity since the first injection, being less than one-third the amount; an injection of 16 mg. was given. This was followed the next day by a temporary increase in sputum and bacillary content (Gaffky 1-3). There was no evidence of general reaction, but he complained of some pain in the region of the left shoulder, which he admitted had been present since the first injection. He had a restless night because of some perivascular infiltration at the site of injection. February 20, 21 mg. given. Seven hours following this rather large dose, he complained of malaise, with occasional sharp pain in the left chest. The next day there was a slight rise in temperature (100.6°), some rise in pulse, and a slight increase in leucocytes. The sputum was also increased. The temperature remained up for four days following the injection. The leucocytes were up for two days, when they fell to normal. During these days he was nervous, slept poorly, had general aching sensations, felt tired, appetite poor, and he had slight chills for two days. There was a feeling of oppression in the chest and an increase of the sputum for four days. His cough had increased; he required heroin for his relief, and there was general depression. On March 1 he felt better, though the cough was still troublesome and there were occasional traces of blood in the sputum. March 6, 13 mg. was administered, followed by some increase in rales, sputum and bacilli. No general reaction. He felt much better than usual and his appetite had improved. March 22, 13 mg., without any evidence of reaction, local or focal. He felt very well and was anxious to be up.

On April 26, examination of the chest showed practically unaltered physical signs. During the treatment his sputum had been reduced to practically negligible quantities. His weight increased from 113¾ lbs. to 121½ lbs. His general condition, physical and mental, was very good, and he was exceedingly optimistic. The reactions following the third injection were probably due to the large dose.

Case VII.—Eva H., age 29, widow, entered the San Francisco Hospital November 1, 1916, complaining of cough, loss of weight, night sweats, vomiting, hoarseness, and occasional hemoptysis. She had been troubled with bronchitis for the past five years and had coughed constantly since February, 1915, with hoarseness. Said she had been run down for the past four or five years, and had had night sweats for the past year. Since August, 1915, she had had frequent hemorrhages, two of them severe. She was about 15 lbs. below her usual weight.

Examination showed a poorly nourished, anemic woman, with excessive cough, emaciated, with extensive bilateral disease, more marked on the left, where the entire lung was involved in a tuberculous process with considerable destruction in the apex. Rales were heard throughout. There was dullness throughout the right upper lobe, with rales at the apex and probable small cavity under the clavicle. The *x*-ray plate showed practically the same extent of disease. The urine, blood, and Wassermann were negative. Temperature was running between 100° and 102°, with very rapid pulse. The prognosis was extremely bad.

Treatment: Treatment begun January 26, 1917, when 12 mg. were given. This was followed by the most severe focal reaction of the series. The next day her hoarseness had increased and there was complete aphonia. Examination of the larynx showed the arytenoids so swollen that a view of the interior of the larynx could not be obtained. The sputum had increased, the cough was very troublesome, and there were extensive sticky and moist rales throughout the left lung. These evidences of focal reaction remained for about 10 days. There was no general reaction. February 9. During the past week she had had an attack of tonsillitis. An injection of 10 mg. was followed the next day by slight focal reaction and some soreness at the site of injection. February 23, 12 mg., with slight focal reaction, as shown by some increase in sputum. Cough still troublesome. March 9. Night sweats had been frequent and severe during the previous week; 10 mg. given, with increase in sputum and cough appearing two days after the injection.

This woman's weight decreased from 104 lbs. to 98 lbs. during the treatment. She became steadily worse, but had been losing ground before. She had been febrile throughout, but during the latter part of the treatment the temperature became higher with more extensive septic swings. On May 1 she was too weak for thorough examination of the chest, but showed that the disease had been progressing. It is possible that she was made worse by this treatment (note the severe focal reaction following the first injection).

CASE VIII.—Minna B., widow, age 25, entered the San Francisco Hospital May 3, 1916. Two weeks before entrance she had had severe hemoptysis, since which time she had had cough and pain in the left side of the chest. She had lost 10 lbs. in weight. She remained in the hospital for five months under dietetic-hygienic treatment, when she was discharged very much improved. Bacilli had disappeared. She was readmitted January 18, 1917, having had several brisk hemorrhages during the preceding two months.

Examination on readmission showed activity on the left side from the apex to the angle of the scapula, with dullness and some rales over the right upper lobe. The *x*-ray plate showed an extensive process throughout the left lung, with the heart shadow shifted to the left—the result of fibrosis. The left lung shadow was particularly dense in the lower part. There was some mottling on the right side, with a few discreet gland shadows. She had a temperature of 100° and pulse of 100. The urine and blood were negative. Blood pressure 120, 83. Tubercle bacilli were present in the sputum, Gaffky 1.

Treatment: On January 26, an injection of 12 mg. was given, followed the next day by slight pain in the chest, but no general reaction or change in the physical signs. January 9, 16 mg. given, followed in two hours by sharp pleural pain in the right side of the chest. The next day there was a definite increase in rales, some of them being moist. Rales were also heard in the right interscapular region, though none had been there the day before. Two days after the injection there was an increase of sputum. Several days after the last injection the sputum was blood-streaked; this was during menstruation, and she had frequently seen blood in the sputum before the onset of her menses. On February 23, a third dose of 16 mg. was given, which was followed by some headache and increase in leucocytes. There was also an increase in the bacillary content of the sputum. March 9, 16 mg., followed shortly by headache and flushing of the face, which lasted all day, though there was no rise in temperature or pulse. The next day the leucocytes were found to be increased; some increase in the cough and traces of blood in the sputum. March 22, 12 mg., without any evidence of reaction. April 6, an *x*-ray plate taken showed practically no change in lung shadows as compared with the previous plate. She had recently developed some edema of the ankles. On April 15 the bacillary content was Gaffky 2, and there had been a slight increase in sputum. The edema was decreasing, though at times she suffered with palpitation and orthopnea, and on one occasion had a rather sharp attack of precordial pain. On the evening of April 29 she had a brisk hemorrhage, 80 c.c. On May 1 another, 60 c.c., and on May 3 still another, amounting to 100 c.c. Since that time there had been no further hemorrhage. It will be noted that these hemorrhages came on after an interval of about five weeks following the last injection.

During the treatment this woman's weight increased from 117 lbs. to 134¼ lbs. This exceeded her highest weight before illness by 5 lbs. Her general condition was very much improved, although probably her improvement was no more marked than on her previous discharge. Very little general reaction followed the injections, but focal reactions were frequent, occurring principally as pain in the chest. After the second injection there was a definite increase in the extent of rales. She ran practically an afebrile course throughout. Bacilli were still present after the last injection.

CASE IX.—Thomas D., an Irish lumber-jack, age 36, entered the San Francisco Hospital January 16, 1917, complaining of cough, weakness, loss of weight, slight hemoptysis, and an ischiorectal abscess, which ruptured spontaneously a few days later. He had been a heavy user of alcohol. Denied venery. He had had pleurisy two years before and had lost 10 lbs. in the past year. Since his pleurisy he had had constant cough, with occasional pain in the chest. Bacilli were found in his sputum one month before entrance. There had been several small hemorrhages since his entrance.

Examination showed a very well developed man, not appearing very sick. The extremities were slightly cyanosed. There was extensive bilateral tuberculous involvement, dullness extending to the fourth rib on either side, with rales almost to the base in both lungs, Although the heart was somewhat enlarged, there were no murmurs. The pulmonic second sound was accentuated. There was a slight amount of sclerosis of the peripheral arteries. The *x*-ray plate showed extensive mottling throughout both lungs, less marked at the bases, with fibrosis at both apices. Blood pressure, 110, 60. The rectum showed a discharging ischiorectal abscess. The urine was negative, with a phenolphthalein function of 50 per cent. Blood and Wassermann were negative. Tubercle bacilli in the sputum, Gaffky 4.

Treatment: Treatment was commenced January 29, 1917, 14 mg. being administered intravenously. This was followed by a slight increase in the cough and sputum, but no increase in rales. On February 12, 19 mg. given. The following night there was some cardiac irregularity, but no other evidence of general reaction. The next day a careful search of the sputum failed to reveal any tubercle bacilli, a gain in weight was recorded, and there were fewer rales. The ischiorectal abscess looked cleaner, and the patient was generally feeling very well. February 26, 18 mg., followed by considerable perivascular infiltration at the site of injection, causing some pain. No general reaction followed this injection. There was a slight increase in rales and sputum. Two days after the injection he left the hospital without permission.

This man's weight increased from 156¼ lbs. to 162 lbs. during the treatment. As he left suddenly, there was no opportunity for examination at the time.

CASE X.—Luella D., age 49, married, native of the United States, entered the San Francisco Hospital December 23, 1916, complaining of cough, pain in the chest and occasional night sweats. A sister had died of tuberculosis, and a brother and three sisters had died in infancy. She had had scrofula at two years of age, typhoid at fourteen, pleurisy at thirty; at about that time she was operated upon for mastoid trouble, the wound of which has never entirely healed. From that time on she lost in weight, suffering at times from stomach trouble, accompanied by cough. Three months before, during sharp pleuritic pains, tuberculosis had been diagnosed. She had always been delicate and subject to frequent and protracted colds. She had been married at sixteen, and three children had died of whooping-cough in early childhood.

Examination showed a woman wasted and bedridden, with a suppurating scar over the right mastoid, chronic pharyngitis, bad oral hygiene. Both upper lobes were involved in a tuberculous process, with considerable cavity formation in the left upper lobe. The *x*-ray plate showed extensive mottling throughout the left upper lobe, with probable large cavity under the clavicle. There was less involvement of the right lung, but there was rather a dense apical shadow and marked peribronchial thickening in the right lower lobe. The

heart was ptosed. Tubercle bacilli were present in the sputum. The urine, blood and Wassermann were negative. Blood pressure 110, 72. Prognosis was bad, in fact, death seemed imminent.

Treatment: On February 1, an injection of 12 mg. was given, without reaction. On February 15, 16 mg. injected, followed the next day by slight increase in leucocytes. On March 1, following an injection of 12 mg., there was a slight chill, and the day following the bacilli were slightly increased. On March 15, 12 mg., with focal reaction the following day, shown by increase in rales, bacillary content of sputum and cough. The next day she felt very well. March 29, 14 mg. administered. This was followed by some distress in the chest and some increase in cough. The bacilli disappeared after this injection and were absent from the sputum until May 1, when they were found again in numbers amounting to Gaffky 2.

She increased in weight from 86¼ lbs. to 91¾ lbs. during the treatment. Examination of the chest on April 27 showed very little change in the physical signs, except that the signs of cavity in the left upper lobe were not as distinctly marked as before. The rales were less abundant, fibrosis and drying up of the cavity secretion had apparently been progressing satisfactorily. The amount of sputum and bacilli, however, were practically unaltered. The general condition was much improved; her appetite was good, she was hopeful, and was convinced that she had derived much benefit from the treatment.

Prognosis for improvement much better than at the beginning of treatment.

General Reaction.—There was little evidence of general reaction in the patients above recorded. Five cases experienced chills, four following the first injection, one following the fourth. These chills were in no instances severe and seemed to have no relationship to the amount of the preparation used.

Rise in Temperature: This was unusual. There do not appear those sudden rises similar to what is occasioually seen following tuberculin administration. Two cases, I and VI, had slight temperature increases. In case VI it followed a dose of 21 milligrams. It was accompanied by a slight rise in the pulse rate and the number of leucocytes. It subsided again in four days. In two cases, V and VII, the temperature rose steadily and was higher at the end than at the beginning of treatment. Most of the patients were, however, afebrile throughout.

Effect Upon the Pulse Rate: Cases I and VI had increase in pulse rate, accompanying rise in temperature above mentioned. Some arrhythmia was noticed in Case IX, following his second injection of 19 milligrams.

Other evidence of general reaction was rare. The leucocytic curve was as frequently decreased as increased. Headaches were observed but usually in cases where headache was a frequent manifestation in the interval between injections. Particularly was this noticeable in Case VIII. Headache, malaise, insomnia, loss of appetite followed the large amount (21 milligrams) given Case VI at his third injection. These symptoms persisted for several days following.

Focal Reaction.—Evidence of focal reaction was very frequent, and was present to a greater or lesser extent in all cases save the one who died. This was indicated in various ways.

Probably the most marked focal reaction was seen in Case VII, where the morning following the first injection of 12 milligrams the entire left side of the chest was filled with moist, sticky rales, replacing the previous crepitation. Hoarseness, almost to aphonia, was also present and the arytenoids were much swollen. These evidences of focal reaction persisted for more than a week. Similar, though not as severe, reactions followed the second injection given this patient. All the cases, except the fatal one, showed increase in rales after one or more injections, but none to the same extent as Case VII. It usually occurred when doses of more than 12 milligrams had been given.

In the majority of the cases there was increase in cough following the injection, sometimes so severe as to require heroin for its relief. This was in quite a number of instances accompanied by an increase in the amount of sputum, and frequently traces of blood appeared. No brisk hemorrhages occurred, except in Case VIII, and in this instance it appeared more than a month after the last treatment. She had, however, a history of several severe hemorrhages before admission.

Sputum was carefully and frequently examined during treatment with reference to bacillary content, the Gaffky scale being used for this purpose. No definite results were derived from this, the count decreasing in as great a number of cases as it increased.

There was pleural pain following most of the injections, sometimes very severe. This usually occurred with the other signs of focal reaction, but frequently it was present as the only evidence.

None of the patients had demonstrable pleural effusion except Case II. Six days after his fourth injection of 12 milligrams, spontaneous pneumothorax occurred on the left side. It was ushered in by a sharp rise in temperature, increased pulse, a slight increase in sputum, and much pain and dyspnea. The next day the sputum had materially diminished. This was followed in a few days by a pleural effusion which gradually absorbed. His temperature remained high for more than two weeks, when it subsided to a point slightly above normal.

General Condition.—All of these patients except Case II showed some increase in weight; not marked in any except Case VIII, the hemorrhagic one, who increased from 117 to 134¼ lbs., which is five pounds above her highest weight before illness. Of course, no deductions can be drawn from Cases III and IX, who left the hospital after receiving three injections each. It is significant, however, that in the first instance there was a remarkable improvement in his general condition, and after the focal reaction following the second injection, the cough and sputum entirely disappeared.

Most of these patients, in fact, all of them, now under observation except the one who had the severe focal reaction following the first injection, and with whom the prognosis was decidedly bad at the start, lay claim to a feeling of improvement and well-being entirely irreconcilable with the physical findings. This is not surprising to any observer who has had much experience with the tuberculous. Aside from the benefit naturally resulting from bed treatment and careful nursing to which these patients were subjected, the importance of psychotherapy in tuberculosis has long been recognized. This fact has been seized upon and illegitimately exploited by quacks for many years. The most

glaring instance of it occurred a few years ago, when the profession complacently allowed the Friedmann fiasco to be perpetrated upon large numbers of these sufferers. I had the privilege at that time, through the courtesy of Dr. Stimson of the United States Public Health Service, of examining a considerable number of these patients. The optimism of these sufferers in the face of rapidly progressive destructive lesions afforded as pathetic a picture as could be drawn before the medical mind of the vicious results of conscienceless press advertising.

As a result of these observations, which by reason of the comparatively short time they have been studied, must be looked upon as a preliminary report, the following conclusions would seem justifiable:

(1) Copper and potassium cyanide in amounts from 8 to 12 mg. in cases of uncomplicated pulmonary tuberculosis is not followed by injurious results.

(2) Large doses, or even smaller ones in complicated cases or those presenting extensive active lesions with fever may produce serious focal reactions causing permanent harm.

(3) Severe hemorrhages are not likely to occur.

(4) Its administration is not followed by severe general reactions.

(5) The preparation is not very irritating to the perivascular tissues if small amounts are accidentally injected into them.

(6) The value of the preparation in the treatment of pulmonary tuberculosis has not been conclusively demonstrated.

(7) Its further trial in the treatment of this disease is justifiable.

233 Post Street.

A PLEA FOR GREATER EXACTNESS IN THE DIAGNOSIS AND TREATMENT OF TUBERCULOSIS.*

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, NEW JERSEY,

CONSULTING PHYSICIAN TO THE MOUNTAINSIDE HOSPITAL.

The writer well remembers his feelings of surprise and incredulity when he was presented with an excellent skiagraph of the thorax of a person alleged to be affected with pulmonary tuberculosis, and was told that certain mottled appearances—which one writer has compared to the eruption of measles, and which were scattered over the lung tissue, being most abundant at the left apex and the root of the right lung—were indisputable manifestations of active tuberculosis. This occurred ten years ago, and I regret to say made only a passing impression on my mind. The radiograph was moved from a conspicuous place in my office to the receptacle which contains the unread reprints and other treasures which are put away in good faith and are occasionally resurrected for some good purpose, always provided that they have not been consumed in one of those semi-annual maelstroms called housecleaning. I desire to pass this skiagraph around; not alone because it so well fulfills its diagnostic object, but because I hope that it may arouse among my hearers some of the feelings of repentance and a desire to shake off the *vis inertiæ* of mental conservatism and intolerance which is so powerful a bar to the general advance of medical thought, and which is often at least the cause of our shortsightedness and ineptitude as clinicians.

Personally, I look upon this picture with shame and humility, because it has taken me ten years to learn the lesson it so obviously teaches and to believe the assertion made when it was given me that the Roentgen ray will establish the diagnosis of pulmonary tuberculosis before auscultation and percussion can do so.

It is perhaps superfluous to call your attention to the now well recognized fact that when a positive diagnosis of pulmonary tuberculosis can be made by the physical examination of the chest the case is no longer incipient, and the golden moment for the institution of successful treatment has passed. If modern medicine has taught us anything of permanent value it is that treatment, to be effectual, must be timely. No one thinks of delaying the administration of antitoxin in diphtheria for one instant after the presence of the Klebs-Loeffler bacillus in the patient's throat has been demonstrated. Nor does any one expect to cure tetanus or rabies after the overt symptoms of these diseases have manifested themselves. In the same manner, no one should expect that the routine treatment of tuberculosis will be invariably successful unless the diagnosis is made and the treatment instituted at the earliest possible moment. It has always been the complaint from the sanatoria that they do not get hold of the patients early enough. Many of us, who do not yet call ourselves old, remember when no one was sure of his diagnosis of pulmonary tuberculosis until the tubercle bacilli had been demonstrated in the sputum. Now we know that while their presence makes the diagnosis positive, they may be absent in about forty per cent. of all cases of consumption. And no good clinician now waits, as we used to do, until the bacilli are found before taking steps to arrest the disease.

The matter of diagnosing pulmonary tuberculosis by the *x*-ray in general practice is at present surrounded by a number of difficulties. The number of good *x*-ray operators is limited. One professor who is using this method, not only for diagnosis but for a study of the progress of the disease in the lungs, has told me that there are few operators who really understand how to take the pictures of the lungs, and fewer still who are able to read them correctly after they have taken them.

Professor Northrup declares that the *x*-ray is his diagnostic sheet anchor, and is more valuable than the von Pirquet test or the swabbing of the throat and nostrils in children for the detection of the tubercle bacillus. He alludes to auscultation and percussion as mere accessories to the diagnostic methods just mentioned. The demand for more *x*-ray operators able to give us these early diagnoses in pulmonary tuberculosis is, therefore, very urgent, and it is our duty as clinicians to insist that this demand be supplied. We must, however, first educate ourselves up to the point where we can read and interpret ordinary *x*-ray pictures fairly well ourselves, and we shall then know whether

*Read before the New Jersey State Medical Society, June 13, 1917.

the *x*-ray work that is done for us by the so-called experts is good or bad. In a recent address, Professor Northrup also laid great stress upon the physical condition of the child. He spoke of the pearly white skin, the languor and want of endurance so noticeable in tuberculosis, as well as in hookworm disease and a number of other systemic poisonings.

Pottenger, in his recent very able address on the perversions of the vegetative nervous system in tuberculosis, insists that none of them are peculiar to this disease, but are to be noted in many other dyscrasiæ and perverted or septic bodily conditions. However, one German writer has recently gone so far as to say that the enteroptotic diathesis and the tuberculous diathesis are one and the same. But in spite of these limitations any pediatrician will, I believe, agree that children presenting these characteristics described by Northrup are, in all probability, tubercular, especially if they have been exposed to tuberculosis in infancy or early childhood. In fact, tuberculous infection is so common that it is safe to assume that any delicate child, and most delicate young people, whose physical depravity cannot be otherwise explained, are infected with tuberculosis.

In examining the chests of such children we may or may not detect any definite signs of the tuberculous process, and the uncertainty and variableness of the physical signs in children make a positive diagnosis of tuberculosis in them, except after repeated and careful explorations, quite uncertain. The child's weight for its height and age, the shape of its chest, its posture, its complexion, etc., should all be given due consideration. If a cough is present, this may be due to enlarged tonsils, but more probably to inflamed and enlarged bronchial glands, which are so frequently the site of the first lodgment in the body of the tubercle bacillus. Enlarged and indurated superficial glands, while possibly due to bad teeth, lues, or Hodgkin's disease, are, if persistent, probably due to tuberculous infection, and if so are easily treated.

Now it is easy to demonstrate the fact that thousands of children infected with tuberculosis never come under treatment in childhood. When they reach adult life, as most of them do, albeit more or less handicapped by the infection present in their early years, a certain large but undetermined percentage of them develop pulmonary tuberculosis. It is quite evident that the golden opportunity to treat and cure these cases has passed. Dr. Hess, the director of the Farmingdale Preventorium, believes that practically all persons with tuberculosis have been infected with the disease before two years of age, and that if babies could be removed from their tuberculous mothers immediately after birth, and kept away from them and all tubercular people for two years, such babies would not contract tuberculosis in after life. Of course, this all sounds rather startling. We all think that we have seen cases in which adults have contracted the disease after exposure to the infection. On the other hand, there is an immense amount of proof that the average adult is, generally speaking, immune against tubercular infection; and the belief is constantly growing that tuberculosis is only developed in the human body after an incubation period of years, and that so-called acute miliary tuberculosis, for example, is never a primary form of the disease, as we used to believe. While the Bang system of segregation has eradicated tuberculosis from herds of cattle, we cannot tell until the experiment has been tried on a somewhat extensive scale that it might not prove equally efficacious in human beings. Naturally, if Dr. Hess's contention is well founded, and he is, of course, only one of many clinical observers who hold the same view, our problem in the eradication of the great white plague is certainly simplified. The carrying out of the scheme in an effective way calls for an expenditure of resources almost beyond our imagination. Still, we shall never conquer this destroyer of our race until we fully understand the magnitude and scope of the problem before us; and this paper is written chiefly as a humble contribution to the problem of how best to descover and handle as many cases of tuberculosis as possible, and what steps we as physicians and philanthropists should take to hasten the consummation of the good work.

My own belief is that every child born into the world should be periodically weighed and measured, and its teeth, bones, special senses, etc., carefully examined. And generally speaking, the child should be submitted to the Wassermann or luetic test, as well as to the von Pirquet or subcutaneous tuberculin test. The feces, urine, blood and saliva should also be examined from time to time, as well as the child's rate of growth, consumption of food, etc. In short, the infant and young adult should be tested out just as an automobile or a ship is tested before it is pronounced perfectly sound. And whatever defects, if any, are noted should be rigidly inquired into in the human being as well as in the machine, and, if possible, rectified in their incipiency. We may not be able to add a cubit to our stature by taking thought, after we have reached adult life, but we can do almost anything to improve the physique, health, beauty and efficiency, both mental and bodily, of our children, by taking thought at the right time. And there is no question that as physicians we shall soon be called upon not alone to prevent disease, malformation, and improper development in growing children, but to give such advice and direction as will insure a better, stronger, and healthier race of men and women than the world has seen since the days of the ancient Greeks.

Just at this writing it would seem that the clinicians and research workers who are fighting tuberculosis are doing more than any other class of workers to improve the human race. We must not wait for the tubercular patient to come to us for treatment; we must seek him out and teach him that every sin against his body tends to put him in a condition where the tuberculous infection which he already harbors in his system will crop out and begin its deadly work. Every one should be warned to keep his or her weight at or near the normal. Obesity, while not so inimical to recovery from tuberculosis as emaciation, is by no means a favorable condition, the popular belief to the contrary notwithstanding. Hence children and adults should be regularly weighed and measured, and any excess or deficiency in bodily weight should be, so far as possible, rectified.

In the von Pirquet tuberculin test in children up

to three years of age, and in the subcutaneous test in all human beings over that age, we have a nearly absolute diagnostic test for the presence of active tuberculosis. These tests should be tried in every case that presents any suspicious symptoms whatever.
